1. Re: Ideas for 75 Meter Homebrew Mobile Antenna?

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-01 00:02:21 UTC
From: Ed Juge/NM <ed@juge.org>
Message-ID: <3d1f9beb.0@oracle.zianet.com>
Source record: 139794

Hi, Chris...

The only "EFFECTIVE" 75-meter mobile antennas I know have large, center-loading coils at least 3" in diameter (up to 5" or more) and are at least 13-14 feet in overall length. A lot depends on your definition of "effective."

If your interest in 75 mobile is casual, a hamstick-type of antenna will make contacts for you at a small fraction of the cost of homebrewing anything... and it's the least obtrusive thing you can choose. Most 75-meter mobilers I know who build their own are using outrageous center-loaded "bugcatcher coils" for the highest level of efficiency they can achieve. And most of them put out 3-5 S-units more signal than the hamstick types. The difference can be even greater measured against plain whips fed with tune-anything tuners. Don't get me wrong... any of these will work and let you make contacts. It depends on how well you want it to work.

By the time you buy or build a sturdy 3-4 foot stainless steel base section, locate a commercial 5-inch diameter coil and build the center insulator and supports for it, you are almost surely going to have more dollars invested (not including your time) than the cost of, say, one of Henry Allen's great "Texas Bugcatchers." A good screwdriver like Charlie Guines' Stealth-4, if you don't mind a $550 pricetag, will do just about the same job AND offer tunability from the driver's seat.

Good luck and have fun!!

73... Ed, W5EJ

Gary, K4FMX wrote:
"Without a balun in the case with coax feed, could there not still be radiation by the coax shield as it could look like and share part of the current that the leg of the antenna is commonwith?"

Yes.

If we have a perfectly balanced dipole connected to coax at 90 degrees, and no balun at the junction, the inside surface of the coax shield has two outlets versus one for the center conductor of the coax.

Without a connection to the exterior of the coax shield, loads on both feedline conductors would be alike. But there are two outlets for the inner shield, the dipole element and the outside surface of the coax.

Inherently, without a balun there is imbalance unless we can make the outside of the coax a very high impedance. Make the outside of the coax resonant, and it may have high enough impedance to balasnce the dipole. A broad-band balun may be more satisfactory if you are interested in more than one frequency.

Best regards, Richard Harrison, KB5WZI

What I am trying to get at is using the example that Gene described
with the transmitter isolated
(battery powered) from ground. Using a quarter wave length feed line
to a dipole with coax and
no balun. It seems to me that there would be plenty of common mode
current in this case.

This would be a situation where there could be common mode current on
the feed line and no
ground path at the bottom end of the feed line. In other words common
mode current doesn't
necessarily have to flow to ground to be called common mode current
does it?

Um, Bill,

It was most obvious to the rest of us that though you fit the
definition, the definition (like the claims of the EH or CFA) did not
fit reality. You have independently proven that the author of the
posting responding to you from an insecure terminal at this aol
address is NOT who he claims to be (and is a masquerader wholly
unfamiliar with the topic in spite of spoofed claims to the contrary).

By-the-by, check the last button down the left at:
http://home.attbi.com/~kb7qhc/
for the download you want, let me know if that works.

Hi Gary,

Common Mode quite often means there is a ground reference involved (although not necessarily). The question to you is just what constitutes the reference (if not ground) of the current you describe such as to make it Common Mode? In other words, just what is the Common you rely on? In a balanced system with differential current, it must by definition be a third point outside of that system. Name the third point (inferences from you argument are presumably neither ground, nor from within the system).

Hello Tom and others,
I will post my last comment here. I don't like to hear your same observations after so many months.
Many of you are just so skeptic , so closed minded , so negative.

1) the CFa can do the job, but there is some inefficiencies. Please go to the antennex archive and look for the "stefano's cfa experiment". Please follow step by step every instruction. The cfa described will be about 0 - 2db to a vertical full size on 7 mhz.
I personally guided a very skilled italian team on it. They duplicated my data.I can still support anybody wants have a try.
Why the entire world is not filled by CFA? good question, but i think to know the answer.
The inventors decided to be "money oriented" only, keeping all secrets, refusing inspections at the antennas sites. In this way all the engineers went to visiting the installations , couldn't check what they claimed...THEN there are some objective inefficiencies.
Is a very long story. the ham tried to investigate didn't want to hear me.
The experiments were quite expensive, so they gave up.
Is much easy to say..is an hoax, than work for almost one year on it as I did.

2) At the moment we sold about 30 antennas. We have 40 more on the back order . we will deliver them the next week.
All, I repeat, all customers were very happy. about 50% of them run a complete test comparing the eh against a full sized dipole.
They were astonished. The EH antennas performed as claimed.I personally follow each customer.

3) I personally have BIG doubts the disappointed hams you are reporting build and tuned them correctely. I am speaking for personnel experiences. I have offered my help to everybody. I am continuoing to say..please let me know ..if you have bad results ,please send me an email, I will drive you in a complete success. You don't have an idea how many mistakes , how many errors for some "fantasy" creations . the eh antenna is a completely new application. Is important follow some rules, but many "skilled" ham think to know all....who is Steve? I am nobody ,in fact, but I know very well the EH antenna, I am one of the two father.Do you want follow me? Ok, you will be successfull, otherwise no way.
Tom, in the Ted's web site there is a complete document about build a 40 meter eh. Ok , please just follow it, if you have any doubts , please ask me. Don't be creative, just follow the instructions and the hints and kinks.
I have big doubts your friends built one of it....

4) the line....another long long story.
you can use 1 ,5, 10 30 meters and so on long line...but the overall performances will be the same.
the antenna 's pattern is quite spherical, there is some radiation toward the line too....hence there is some rf field coupling with the external coax shield. having a good rf ground in the shack is possible to fix all...
again....you can use 1 meter, half meter of line and the eh antenna will perform the esame, ok?
The EH natenna use a phase to work...the use of ferrites or baluns or....can cause a phase shift to the antenna connector. If you don't compensate it, the antenna stop to work.....you must retune the network, my be change it....but nobody wants hearing us about this topic....we are fool, we are stupid we are speaking of non sense ....and so on....
NO, the reason is different, we have something completely new here, is not on any antenna's book.

simply do this:
connect a EH antenna directely to the rtx with a angle connector, then power it using a CAR battery.
Put all this stuff on a roof or at 5 meters from ground.

where is the ground?
where is the line?
no line, no ground. ok the antenna will perform perfect. I verified it many times.Try it.

5) the entire EH antenna research costs money, a lot of them.
we invested , we have a factory, we have the man workers, we are partecipating to many ham fairs, we are spending money to advertising..do you really think we are stupid?
I could sell one antenna....but then???? if it was an hoax, the day after I would have the antenna back for sure....
where is the benefit? No guys, the EH antenna is real.

I have so many happy customers comments . Please have a look on the www.qrz.com forum at "it really works" .
there are so many american hams experimenting with the antenna, mnay of them are astonished, reporting excellent results.
dear friends you are not updated, there are hundreds of happy EH antenna users....We need just time...you will see it....
The concept is spreading out in Europe....now....

I want attach here one of so many good reports I am receiving daily.

Hello Stefano,
Some progress at last, the rain held off long enough to conduct some on air tests last night.

This is 80 meters, 160 mm pipe, 340 mm elements spaced at 160 mm.
Antenna at ground level
power 10 watts SSB

Comparison Antenna at this QTH --- 2 x 60 foot doublet at 25 feet above ground fed with 600 ohm open wire
feeder
same power to both antennas via coax switch.
further tests will be made with each antenna connected to the TX/RX on its own to ensure that
one ant does not influence the other by having the coax shields connected together by the coax switch.

Distance to other station is only about 8 Kmeters, due West of my QTH
Antenna at other station is 2 x 90 feet doublet fed with 600 ohm open wire at 30 feet above ground.
Both doublets run North - South.
On these first tests the other station had no idea which antenna was in use until the conclusion of the tests.

2:1 SWR points are out of band in that the low is around 3.480 MHz and the upper is 3.820 MHz
1:1 is at 3.620 so not quite symmetrical.

After the tests were completed and the other station reported his findings only then was he informed which antenna was which.

Conclusions
On transmit from Me to remote station
remote station reported :-
antenna 1 readable S 7
antenna 2 readable S7-8 and audio sounded much better than Antenna 1
Very High noise levels were apparent at this time of test -- 19:30 GMT.

Received signal from remote station at my QTH :-
antenna 1

Just readable, s meter at S9 noise report given 3-4/7
S meter did not move from noise level of S9
so the report was a guess!.

Antenna 2
noise level S0
received signal report given 5 /7 perfectly readable
with no difficulties.

Antenna 1 was the doublet
Antenna 2 was the E-H

I have experimented with different coil turns and capacitor values.

given the sizes of pipe and element size What number of turns and what size of capacitor do you recommend for 80
meters?????

Hope this info is of use

Mike

MM3EIY/GM8FYJ

---

ok is just an experiment....but I hope you noted what kind of
results....!!!!
for me is normal, I received so many like this one.
You can't explain such results with the Hertz antennas theory.

humilty, humilty this is the problem.
I can understand....I am just a dumb italian, spending countless houres
investigating on some crazy antennas.
Ok , we are giving the possibilities to everybody, without any secrets, to
see a real news after 100 years in the antennas.
Do you prefere talk and talk, without try it? Ok you are free to do it, but,
please don't comment. IF you don't see it you never believe it . two years
ago I decided to go deep and deep on it. I was right and now I am trying to
help any ham , sharing with everybody what we have learned. It's free.why
not?

I am still available to help everybody to have a working EH on hands.
For those still saying is a waste of time, I can't do anything.we are living
in a democracy.
Sincerly stefano (steve) IK5IIR

>mode currents, they are even phase locked.

They are phase locked because they come from one generator or source,
not because they are directly related in impedance values or
interaction.

One case or even a dozen cases where something through a random set of
circumstances tracks does not make it a "rule" when there are clear
exceptions the model does not account for.

I find it ironic and frustrating that you picked at me for an example
that IS always true withing the boundaries I gave, then take liberty
to make a rule without clear well-defined boundaries and dismiss
counter-examples with "well, they aren't common antennas". The
sideways thinking that common mode and differetial mode operation is
directly related is why you were wrong about the tuner, and took hours
to budge from that position.

Thank you Richard,

I have been following the arguments of moving the balun from one side of a tuner to the other on
these threads. I am trying to sort out fact from fluff.

As Richard Clark asked of me, "what is the third point". I am looking at the current on the coax
outer shield that is originated at the junction of the coax and antenna connection. Whether or not
the opposite end of the coax (where the transmitter is) is grounded or not there can still be
current on the coax shield as you have stated. From all the discussion that has been going on I
am taking that current to be called common mode current.

Let's say we have a 1/2 wave antenna and that a balun is placed at the antenna and a tuner right

behind it. That is fed with coax cable. Swapping positions of the balun and tuner should make
little if any difference in what is called common mode current as there is going to be about the
same impedance on the input of the tuner as there is on the output of it.
.
But if the antenna is a full wave antenna and the balun is at the antenna then the tuner, the balun
is going to be at a high impedance point and less able to reject the common mode current
because it has a lower relative impedance. Now put the tuner at the antenna then the balun to
the coax. Now the balun is operating at a much lower impedance (it is seeing 50 ohms of the
tuner input) than it did when it was at the antenna.

Wouldn't the balun be better able to reject the current that would flow on the feed line in this
case?

Isn't this similar to tuning the frequency up or down from resonance of the antenna when just a
balun is connected to the antenna. In this instance as Cecil has said the common mode current
increases because of the change in load that the antenna presents.

Not trying to re write anything here. Just trying to understand what has already been said.

Thanks
Gary K4FMX

interaction."

No interaction?!

The unbalanced differential-mode signal and the common-mode signal share
a mutual impedance in the exterior of the feedline.

Evidence of mutual impedance is current in one element caused by voltage
across another element, or voltage across one element caused by current
in another element.

Current in an unbalanced antenna places common-mode voltage across a
feedline.

Gary, K4FMX wrote:
"Using a quarter wave length line to a dipole with coax and no balun. It seems to me there would be plenty of common mode current in this case."

A 1/2-wave is resonant in the "free-space" example Gary proposes. The exterior of his 1/4-wave coax is directly connected to one element of the dipole. This element is also a 1/4-wave. This combination makes a 1/2-wave Vee. It is resonant and susceptible to excitation.

I was surprised that the loss was that much, but it appeared
consistent.. The method was less than scientific, but was as good as I
had available. I'm glad to hear that it was likely wrong - on that side
of the scale.

Gary, K4FMX wrote:
"As Richard Clark asked of me, where is the third point?"

Look at the dipole/feedline point. One side of the dipole and the coax exterior are common. They share the other side of the dipole as the other "half" of the antenna.

How can they come from one source, be phase locked, and still be unrelated? Your example of a feedline coming off at a 45 degree angle proves that even you know how to turn differential currents into common mode currents. We know a number of things we can do to a system to minimize common mode currents. If common mode conditions were unrelated to differential conditions, taking those steps would not accomplish anything.

And I never said they are "directly" related. They can certainly be indirectly related as in the case of inducted currents. But you said they are "not related" and refuse to budge from that position. As I said earlier, we are just going to have to agree to disagree on this one.

Bill:

A loss that needs to be considered when using a tuner is increased transmission line losses. Even though you get a good match with a tuner, the losses in the transmission line increase with increasing VSWR of the antenna, even though your tuner gives you a good match at the transmitter. The ARRL antenna handbook has curves for this. An example. If the VSWR is 2:1 at the antenna, and there are 3 dB of transmission line losses (from transmission line tables or measurement in a matched system), the experienced losses will be about 3.3 dB. This isn't bad. If the VSWR at the antenna is 10:1 under the same conditions, the loss experienced goes to about 6.7 dB. With a 20:1 VSWR the experienced losses goes to 9.4 dB. You need to consider this phenomenon when using tuners with mismatched loads, particularly with random wires and mobile whip antennas that are not resonant.

I shipped an oversized vertical antenna a few months back by UPS. The oversize charge was not too bad, but they stick you with something I think they called a density charge. They have some sort of ratio of volume to weight. They figure that any given volume needs to have a certain amount of weight. If you have a light bulky item, you are taking up space they could be filling with more packages from other customers. Because of this, they charge you for the weight that would normally fill that space. I ended up having to pay for 30 pounds when the packaged antenna only weighed 10 pounds. Fortunately, I was only shipping it a couple of hundred miles.

Gary, K4FMX wrote:
"Swapping positions of the balun and tuner should make little difference in what is called common mode current as there is going to be about the same (common-mode) impedance on the input of it as there is on the output of it."

Well said.

"But if the antenna is a full wave antenna and the balun is at the antenna then the tuner, the balun is going to be at a high impedance point and less able to reject the common mode current because it has a lower relative impedance."

Certainly true when the balun is at the antenna. Feedline length could make things better at the tuner for balun placement with the balun`s limited inductance as an opponent of unbalanced current.

"Now put the tuner at the antenna then the balun to the coax. Now the balun is at a much lower impedance---."

That`s it! The balun can be effective with an ungrounded tuner. The balun shouldn`t be overstressed and the coax should not radiate or burn Cecil`s lips.

One problem is access to tuner adjustments. Cecil`s plan for controlling impedance on the earth end of the aerial feedline may be a way to bring things down to earth.

Are you referring to the June or July issue? I have the July issue, and there are several ads for "apartment" / mobile antennas. The MFJ-1622 has sparked my interest. If you could tell me more information about this antenna, such as where in the QST mag, that would be great. Like I said, I'm new to amateur radio, and I am learning from every post. I would really just like a HF antenna that can be put up and taken down quickly.

I also want to thank everone who has replied to this post so far. The posts have given me more ideas and options on how to accomplish HF "stealth" hamming operation. Of course, the more ideas the better.

> seeing 50 ohms of the
> tuner input) than it did when it was at the antenna.

I apologize if I am the source of this misunderstanding. Tom's explanation made me realize that moving the balun/choke doesn't move the unbalanced/balanced junction point. If the balun is the only thing that changes position, whatever conditions existed conducive to the origination of conducted common mode currents still exist at the same unbalanced/balanced point no matter where the balun/choke is located. The principle is easy to see in the following examples:

XMTR------------coax-------choke-x-------ladder-line-----balanced antenna

XMTR--choke-----coax-------------x-------ladder-line-----balanced antenna

Even though the choke has moved, the problem area continues to be at point (x) and the stress on both chokes originates at point (x). And I am not saying that the common mode currents would be equal in the two cases.

Hi all,

I have updated my web page with an Excel sheet to calculate a Coax Monopole for short wave. I am using such antennas for 17 and 20 m and worked from OE portable a lot of Eurpeans and a W3 - with 5 watts only!

Have a look and have fun! http://www.qsl.net/oe1mww/ and go to 'station'. The antenna info is at the bottom of the page. Download the .pdf and the .exe or the .xls to make your own design.

Feel free to contact me at oe1mww @qsl.net (remove the space before the @)

The IMPEDANCES and INTERACTIONS with regard to voltage and current,
which is at the root of the whole discussion, are unrelated.

You keep trying, because the same source supplies energy, to tie them
dorectly together in some sort of unbendable relationship...which is
what continually gets you in trouble with sssystems like baluns and
tuners.

Good night Cecil, go play head games with someione else.

Oh, I think that's exactly what I 've made on my web! read it!

> The EH antenna is ....
> The EH antenna is ...db under....
> and so on...
> first of all we should be professional.

I'm sorry, if somebody will pay me, I'll be professional,
for the moment I just enjoy "playing" with EH.
By the way, my aim was simply one: compare the EH with
a common antenna for 160 mt (a 10 mt vertical);
If what people say about EH is true ("it performs as well as a full size
dipole"),
then I'll be the first to use EH instead of other antennas;
but at moment these are my results, and they say to me that
EH does not perform as well as a full size dipole;
I'm not sure (at present time) if these results are due to a my mistake or
not,
but a friend gave me his "original" EH (made by you) for 40 mt band for some
week;
when I'll have free time, I want to compare it with a horizotal dipole and a
1/4 lambda vertical;

May be that's the only way to see if EH "performs as well as a full size
dipole" or not.
ciao

>Hello Tom and others,
>I will post my last comment here. I don't like to hear your same
>observations after so many months.
>Many of you are just so skeptic , so closed minded , so negative.

It is your opinion the rest of the world is closed minded:

1.) It is your team who refuses to provide an antenna that we can compare in a test. You say you have them working, and I will pay you $10,000 if you bring one here that ties or beats my monopole. (Feedline radiation is NOT allowed, the antenna must radiate) All you need to do is pay me for the engineering time at $100 dollars an hour if it does NOT.

If I had an antenna that worked, and lived only 50 miles away (like Hart does) I'd throw it in a car and make a quick $10,000 dollars.

2.) It is your team who dismisses the many tests that can not make your antenna work. Is your antenna simple to build and make work, or is it not? Which is it?

3.) It is your team who keeps saying "we have an antenna that works" and a few minute later changes it to "you will see as soon as we get one working" Which is it? Do you have one working, or do you not?

4.) It is your team who can not answer simple technical questions, like how it is possible to feed a two-terminal system (a dipole) with current in each half 90 degrees out-of-phase from voltage and have NO reacytance at the feedpoint and no common mode current making the feedline radiate.

5.) It is your team who thinks radiation comes from electric and magnetic static fields, and not charge acceleration. Nothing in physics agrees with that. Fields are ways we explain interactions of charges, they are NOT the cause of interactions.

6.) It is your team that dismisses clear signs the feedline is radiating, such as reports of severe RFI when the feedline is near noise sources.

>1) the CFa can do the job, but there is some inefficiencies. Please go to
>the antennex archive and look for the "stefano's cfa experiment". Please
>follow step by step every instruction. The cfa described will be about 0 -
>2db to a vertical full size on 7 mhz.

Just a few years ago, Ted Hart and others in your group proclaimed the CFA a working system. They reported it worked as claimed, which was several dB above a full size antenna.

After selling plans for money to people, it was suddenly declared the CFA does not work as claimed, and is impossible to build because it is "too critical to adjust". The EH was the answer, easy to build and full efficiency.

Now once again, no one else makes one work. Only the people selling the idea.

HOW MUCH MONEY WAS RETURNED TO PEOPLE FROM THE CFA that did not work?

>I personally guided a very skilled italian team on it. They duplicated my
>data.I can still support anybody wants have a try.

Where is this "skilled team" and antenna, and how do you train to build an antenna? The only working CFA is in Egypt, where is the working EH antenna hidden?

>Why the entire world is not filled by CFA? good question, but i think to
>know the answer.
>The inventors decided to be "money oriented" only, keeping all secrets,
>refusing inspections at the antennas sites. In this way all the engineers
>went to visiting the installations , couldn't check what they claimed...THEN
>there are some objective inefficiencies.

There may be other reasons why engineers could not check. As I understand, they never let them look at the feedlines or power in feedlines. They only allowed them to measure FS at a distance, and not actually see what antenna was being used.

Allowing someone to see what feedline has power, or to sniff RF around the feedlines is NOT keeping a trade secret. It is hiding something else, not technology!

One early report that said the system was measured by an independent source showed the CFA 10 or more dB down from a normal antenna. Perhaps that is the real reson why no one was allowed to make further measuremnents near the antenna.

That may also be why no one is allowed to see a working EH antenna in a test environment.

>Is a very long story. the ham tried to investigate didn't want to hear me.
>The experiments were quite expensive, so they gave up.
>Is much easy to say..is an hoax, than work for almost one year on it as I
>did.

So you have a simple easy to build broadband antenna that takes the only people in the world who know how it works one year to make work.

If I took one year to make a simple antenna with two or three coils and two capacitors and two pieces of tubing work, I'd go find another

occupation!

>2) At the moment we sold about 30 antennas. We have 40 more on the back
>order . we will deliver them the next week.
>All, I repeat, all customers were very happy. about 50% of them run a
>complete test comparing the eh against a full sized dipole.
>They were astonished. The EH antennas performed as claimed.I personally
>follow each customer.

Please publish some names, or better tell us where to see one. If you have them working, why not bring one here?

I will pay all the costs to test an antenna in an accredited lab recognized to do this work professionally IF the antenna works as claimed, and the feedline does not radiate. If it does not work as claimed, YOU pay all the costs for everyone. Isn't that fair?

>3) I personally have BIG doubts the disappointed hams you are reporting
>build and tuned them correctely. I am speaking for personnel experiences.

I have big doubts the antenna works as claimed. We are even.

The proof is seeing one.

>5) the entire EH antenna research costs money, a lot of them.
>we invested , we have a factory, we have the man workers, we are
>partecipating to many ham fairs, we are spending money to advertising..do
>you really think we are stupid?

Yes, I do. Very much so.

Anyone who thinks a two-terminal load can be fed with 90-degree phase differences must be stupid.

Almost anything will radiate. Many people love antennas that are ten or more dB down from a d ipole. For example, you will find many B&W dipoles used on 80 meters or 160 meters, where they are 10% efficient and people love them.

You will find people who swear by the Gap antennas on lower bands, even when they measure nearly the same amount down from a conventional vertical.

You will find people who love the Sommer T-25, even though it is very inefficent on lower bands.

I make contacts with Europe and Australia on my small mobile antenna on 160-meters, and it is only 1% efficient. I could invent some big lie, and sell them and many poeple would be happy.

People pay hundreds of dollars to change PIN diodes in radios, when it makes no difference in performance.

Finding people who are happy with nothing or very little is not difficult to do, if you sell them that something works with enough

confusing stories about how wonderful it is. For example, people purchase magnets for fuel lines to improve automobile efficiency and even purchase little propellers to "supercharge", and if you ask them about hald say they work.

If you measure them, none work and some actually hurt.

What matters is how truthful the stories are.

Where can we see an antenna that works in a fair A-B comparison? Name a big technically skilled person with a history of being reliable who has one that works.

The db losses on the transmission line remain the same on the line
regardless if a tuner is used or not. If there is any increase in loss
it is because you are now putting more power into the system, but the
ratio remains the same.

The question should be how much more power am I radiating on a given
system with a tuner than without.

Additionally, losses are also frequency dependent. For example, using
a 100 feet of RG-213 on 80-meters a SWR of 10:1 will produce an
additional loss of of only 1 dB due to SWR. Re: ARRL handbook.

> AT-11, to it. ...

I used an ICOM remote *antenna* tuner - not the coax tuner - mast mounted under a bug catcher to make over 100 EZ contacts on field day. It tuned from 6 thru the very top of 75 with the coil tap on 20M and from 10 thru 75 with the coil set for 40M. Prolly *not* the most efficient setup but couldn't beat it for convenience: turn the knob til you heard somebody, punch the 'tune' button, wait a sec, then talk ... just like FM.

If you buy an R* from Cushcraft, I hope you have better luck with it than I did. After working with them to get it to work, they sent me a new one which I gave (!) away. Someone here suggested you use an Icom AH-4, but there are several others that work as well. You can get real creative running a long wire with parts of it vertically mounted, and some horizonally mounted, sloped, what have you, and use the tuner to tune it to the band you're on. You might just be surprise how good it works.

Alan, Kï¿½BG

46. Ideas for 75 Meter Homebrew Mobile Antenna?

Newsgroup: rec.radio.amateur.antenna

Source record: 139747

Looking for ideas and construction info on making an EFFECTIVE 75 meter mobile antenna to mount either on a bracket attached to a Thule bumper hitch type bike carrier (described below) , or on a military type antenna base mounted on the side of a stake bodied utuilty trailer towed behind the subject vehicle (97 Taurus Wagon). I have a two section nominal 10 foot fiberglass military whip (the ones you see on Humvees with the big rubber tip) that I am considering using as the basis of a center loaded 75 meter antenna. Would like to use something high Q like 1/4 inch OD copper tubing for the loading coil.

BTW, the Thule bike mount has proven a very effective installation for Hamwhips on 40 through 10 meters, allowing me to work worldwide with a Yeesu FT-100D. I use an L bracket from a trucker type mirror mount, bolted to the top of the nominal 3 foot long 2"x2" pedestal of the bike rack. A small plastic enclosure near the feed point allows for feed line termination as well as housing any required feed point shunt capacitors (500 pF on 40 meters). To keep the installation clean looking, I have removed the actual bike rack hardware from the pedestal. The feedpont for the whips is about 4 feet off the ground, and gets the whole antenna way up and in the clear with slight rake to aft. Heavy wire is used to bond the pedestal to the hitch frame as well as directly to the vehicle body.

47. Re: CAM?? Parallel dipoles for 80 m and 40 m?

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-01 13:37:17 UTC
From: k0bg@aol.com
Message-ID: <20020701093717.08903.00002493@mb-mw.aol.com>
Source record: 139688

Cam's explanation is as good as any I have seen on this newsgroup recently. His remark about interaction is correct, and if you can, run the legs inan X figuration, as this will minimize the interaction. And don't be afraid to use coax, even if the VSWR is rather high. The additional losses due to high VSWR isn't worth worrying about, even on 10 meters.

Most antenna tuners use some sort ob 4:1 balun, and contrary to popular opinion, they DO NOT handle high VSWR very well and actually add more loss than using coax without the balun!

My doublet (dipole if you please) has two dipoles, one for 80 and one for 40. It also has pigtails hanging down approximately in their centers. The resonant VSWR on all bands from 80 thru 10, except 12, is less than 2.2 to 1 which the auto tuner handles very well.

Best advice? Hang, get it close to resonance, use the tuner if you have to, and just have fun.

Alan, Kï¿½BG

>Do yourself a favor. Go buy a good ballmount and drill a few holes. The
>difference in performance can be dramatic

As will the bill when the lease car is returned (per the contract we have w/our leasing company, in the range of $1000). I was following the question...some folks CAN cut holes, obviously much better for performance, but some can't have such mounts.

I'd love to mount something better on the plastic Poncho I have, but the only way is with a mount running from the frame under the car, around the (plastic) bumper and then up...NOT a good situation. Trunk mounts are the quickest way w/o welding up a major bracket (which I may do anyway....anyone have any spring steel?) Look at the new Pontiac Grand Prix, you'll see what I mean.

Cheers!
Andrew

This is a well know problem with Toyotas as it is for Fords. Call Palomar Engineers, 760-747-3433, and buy 3 or 4 split beads and their covers (FSB-1/2 and SBC-1/2) These are the 1/2" ones, and they also have 1/4" which are a little small for the Toyota, but work on the Ford. Forget the caps, they don't work. Mount them as close to the tank-mounted fuel pump as you can, and if your's is one with an extra long ground wire, shorten it as much as you can. You will not make the noise go completly away, but S1 is better than S9!

If anyone reading this has a Ford, see my comments about the problem on eham.net/forums,mobileham.

Not true. All you need is an SWR meter. MFJ has one for as little as $34.99,
part number 816. Adjust the antenna for maximum power forward, minimum power
reverse. See http://www.mfjenterprises.com or http://www.aesham.com for the
meter.

Or, if your transceiver has an SWR meter built in, that will do fine.

The antenna has two traps on top for 20 and 30 meters. It uses the whole thing for 40.
For the higher bands it uses resonator stubs like the old KLM beams. On 20 it compares well with a dipole.
The 6, 10, & 15 meter stubs and 20 meter trap seem redundant, since an end-fed half wave also works as an end-fed full wave.
It's heavy and long and needs a good mount. Mine fell in a storm, breaking off the traps.
I'm removing all the stubs and silly hats and will resurrect it for 20 (1/2 wave) and 10 (full wave) only.
Seems to me with a little thought you could use all bands with less of the junk with which they cover the antenna.
If I were you, I'd see if I could come up with an invisible wire loop.
Save the money for beer, I wish I had.

Source record: 139695

Hi Kes

I know! I'm one thread off<G>

Years ago, I made a small loaded 10/20 meter vertical and disguised it, using plastic leaves and brances (with the wires pulled out) to resemble a small tropical palm tree. The antenna mast was covered with glued on cotton balls and small pieces of styrofoam, then wrapped with brown florists tape. This tape is dark brown until stretched, then it becomes light brown, so you can stretch more or less to get varying colors along the trunk of the tree. The purpose of the cotton balls and styrofoam pieces glued to the antenna was to give it the appearance of a regular palm trunk.

I also did a Copper-Cactus sculpture for a VHF/UHF multi-band and a Birch tree for a six-meter antenna.

An abandoned telephone line (already up, compliments of Ma Bell) but disconnected at the pole, was converted to an 80 meter dipole. As luck had it, a tree was close enough to the center that I could run the feed coax down the tree and underground to the shack.

The longer I lived in these apartments, the larger my antenna farm grew. Still undiscovered, I kept getting more brazen and eventually installed a whole radial bed and a fairly well exposed vertical. I disguised the traps near the base by building a small wishing well type fountain, that drew your eye away from the tall vertical portion above the roof. I couldn't believe the things I was getting by with.

You just don't know until you start trying things. A slingshot or bow and arrow make a great tool for getting a nearly invisible dipole up really high, that passes over your apartment property. If you use utility poles, expect these dipoles to be cut down by the utility companies. But neighboring trees are fair game. Hey, fly a kite and lose it in the tree and leave a string dangling. People become used to it and don't pay attention after about a week. That's when you shoot the guys for the dipole up over the treetops<G>.

I've used a K400M for many years. It works fine...never had any problem.

58. Re: CAM?? Parallel dipoles for 80 m and 40 m?

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-01 17:56:28 UTC
From: John <my-callsign@qsl.net>
Message-ID: <ZJ0U8.3439$fe.91652@news8-gui.server.ntli.net>
Source record: 139699

I have the five dipoles supported from two 15ft. fiberglass fishing rods that our joined together, end to end, on a wooden (well varnied) T piece that also has two U bolts through it to connect to the mast.

I tuned the dipoles on a 12ft pole at gound level starting with the 10mtr one and working up in wavelength. For this I used an MFJ259 analyser. When I mounted the dipole up at 28ft the resonant frequencies went up between 50Khz (20mtrs) and 200KHz (10mtrs). I'd bargained that this would happen (from my Mark 1 version) so deliberately tuned them low in frequency. Mark 1 version was just for 20/17/15 and can be seen here:
http://www.qsl.net/g4irn/parallel_dipoles.htm

I put the dipoles up - SWR less than 1.7:1 on all bands (though only about 300KHz is useable on 10mtrs).

Hope that's of use..

Hi,

If assembled properly, a crimp type connection is just as effective as a soldered connection.

Not everyone can solder these connectors properly, or like myself, my arthritis prevents me from using the soldering iron. Back when I used to make many of these connections.

BTW, why the need to reference CB or 'cheap' for crimp connectors ?

Many production radio has crimp connectors.

regards,
richard tracy

I had one and liked it very much. It took a lightning
hit though and I discovered that Cushcraft was not
good with spare parts for new antennas. I am presently
using an R-7000 and like it too. If I had to buy a
new antenna though, I would probably buy a Hy-gain
simply because parts are more readily available.

good luck & 73,
Phil

Source record: 139702

JIm:
I bought a Diamond K400-3/8" at Dayton this year, and put it on my wife's 2002 Camry for a trip to the Maritimes.
I used a 20M & 17M Hamstick feeding them with an FT-817 & MFJ 971 tuner...worked a number of DX stations, and anyone with a 5 X 7 signal. 50 - 100 W in the vehicle is the way to go...5 Watts works but have to "earn" your contacts! Oh Yes, make sure you tie some fishing line from the antenna to the vehcle to take up the strain from speed. I really would not want to trust any trunk lip mount ALONE!

By the way..I also bought an OPEK Trunk Lip Mount for $15 at Dayton..NEW. When I got home was curious about the difference between the Diamond & OPEK. Was very surprised to find that that on the Diamond, there was continuity between the shield on the coax and the ground side of the 3/8" connector mounting plate..BUT.....the OPEK had NO Continuity between the mount screw and the adjustment bolt..and nothing to the mounting plate where the Connector would be placed.
I have to investigate further, but appears that OPEK is using a non-conducting material to make thier mounts...
Can anyone else confirm or deny this?

Source record: 139704

Hi Len:
The Cliff Dweller Antenna would not be suitable for an apartment, as I is quite LONG. It was designed to operate on 40 & 80 Meters Only...but would work at 10 Meters.

I picked up 3 parts of this interestingly designed antenna, but am MISSING the centre part with the motors...the most important part. Have also obtained some Techical Information during my "searching".

If you can advise who was selling the Cliff Dweller at the Auction, I would appreciate it.

I have been Emailing with a couple of other chaps in USA, who are bringing this antenna out of mothballs, and getting it operational.

If anyone needs more info, perhaps we can exchange whatever data we have among ourselves.

Hi Francesco,

Your link to iz7ath, Talino, goes again to confirm that the EH is a
tuned top hat to a coax monopole. Unfortunately tuning does not
impart the same benefits of his simple monopole with top hat (in other
words, the EH makes a poor top hat).

Hi Talino,

Your work far exceeds the poor effort shown by those who proclaim the EH the loudest. Your pages are clear and well designed. The photos are crisp and well sized showing all detail. You also handle your mistakes honestly and correct them. Bravo!

One question, I may have missed seeing it, but did you apply a W2DU style balun to the feed point of your EH? Did you examine the feedline for current?

My reading of your analysis was that as you raised the EH, it improved - but not to the quality of your other short vertical. This would suggest your feedline was becoming a radiator if it does not have isolation from the drive point. The correlation between improvement and height also points out that it is still a poor performer without the top hat.

I have a Diamond K400 on my car. I use an Outbacker Perth on it. The
mount was bought in 1996 and is still as good as new. I did have to
shorten the minicoax twice because it got stuck and damaged. It's
attached to the hatch (or whatever you guys call it...) you can see a
picture on: http://www.qsl.net/on4bam/html/scotland1.html
I also use a 'guy wire' as extra support for the antenna and to keep
the stresslevel down on the mount at (German) highway speeds.
I also used the mount on rental cars in W and ZS.. The only thing is
that you need to make a good connection to bare metal (ground)with the
4 screws. You'll notice a bad ground immediatelly .. higher noice
level and SWR problems...

Bye Maurice

>There is NOTHING new under the sun!<

When it comes to antennas, I think you're right! Regardless of the author's rather novel interpretation of antenna theory, he still has a capacitively loaded asymetrically dipole. Collector? Generator? What's that all about? Think I'll re-designate the wire on my 80-meter dipole as a "Conduction-Based Electron Accelerator" and patent that! It's actually a much easier concept to defend because it's closer to reality! Goofy, this antenna business.

Get some small gauge wire. hook one end to the antenna connector of the
radio, and the other as long and clear as you can, outside preferable.
Inside if needed.

Check the specifications, or do some tests yourself on crimp connectors and the so-called "field serviceable" connectors, and note the differences.

Commonly, the braid attaching mechanism of crimp connectors is stronger, reducing the likelyhood of the cable being pulled out of the connector. (Check the specs on BNC for instance, it is not unusual to find that the crimp connector is rated at ten times the field serviceable).

Crimp connectors aren't necessarily cheap and nasty, but there are plenty of particular implementations that are a waste of money. Quality crimp tools are precision tools and are expensive, althogh it is possible to get medium cost tools that do a pretty reasonable job.

So, it is the old story to some extent: quality articles sustain higher prices.

The main arguments against crimping would be the cost of good tools, and the need to trim the cable correctly first time. Although weatherproof crimp versions of many many connectors are available, they are more difficult to obtain and one may often choose field serviceable connectors for weatherproof applications.

So, it is not so much that the RF performance of a crimp connector is better, but that the RF performance of a cable where the braid remains properly attached is better.

For my application, I am usually influenced by the better reliability than the lower cost of installation - that is a bonus.

If your experience is mostly about soldering PL259s onto RG8, then you might not appreciate much of this!

Year after year, I am tired of hearing and reading about the G5RV.

Insofar as G5RV's with their half or double-sized versions are concerned, it is recommended you make your minds a blank.

The Guru's, old wives and plagiarists interminably continue to propagate its special magical Marzipan properties to bolster their ego's and imagined reputations.

Most of these cranks are fully aware the G5RV has no better performance than any other multi-band, crudely omni-directional dipole, of random end-to-end length, fed with a random length balanced line of no specified impedance.

In fact it has a sub-standard performance if that attention-attracting length of coax is insisted upon just to retain the name.

I'm quite sure G5RV would agree if he was still around. It was others who have made a few bucks and are still attempting to make a few bucks out of suckers from his description of a simple basic, rather obvious dipole which had been around for years before his first relatively unimportant article on a one-band antenna.

It does at least work very well compared with the much-later cross-field and related inventions.

Its history has been turned into bunk by salesmen, magazine editors, authors and the antenna newsgroup establishment. Now let it rest in peace.

That's my unimportant two-penny-worth contribution anyway.

Last I saw on TV, ole' Heff (not to be confused with Henf or hemp) was looking for ways to make things taller rather than shorter. His "associates", aparently tired of lumped loading and fractal geometry, resolved the situation by giving him a new prescription for happiness.

UnTale wrote:
"May be that`s the only way to see if EH "performs as well as a full size dipole" or not."

Daytime 160m testing of a vertically polarized EH antenna against a horizontal dipole is flawed.

Signal from the horizontal dipole is limited to the line of sight over good ground during the day.

Signal from a vertically polarized antenna propagates beyond the line of sight via the ground wave.

Please see Terman`s 1955 edition of "Radio and Electronic Engineering" page 803:
"The ground wave is vertically polarized, because any horizontal component of electric field in contact with the earth is short-circuited by the earth."

Best regards, Richard Harrison, KB5WZI

Well, what do you want him to do, lie about it? In his tests, the EH
was beaten by the other antennas. None of which was close to being as
efficient as a 1/2 wave dipole. Even his short vertical seemed to beat
it quite handily. And there is no way on earth that vertical he used
is as efficient as a dipole. It was short, and used a "marginal at
best" ground system. IE: 4 uneven length radials. But the real kicker
was the change in performance when he added the choke at the
feedpoint. Didn't look good. The feedline is obviously radiating.

He did mention adding a choke at the rig with no change. "naturally".
And he then said he added a "bead" type choke of some kind at the
feedpoint, and the antenna did go to heck...SWR wise, and performance
wise. The feedline is radiating. No doubt about it. MK

<rmowery@dialpoint.net> wrote:

If you have or can borrow a second tuner of the same type, connect them back to back. Connect one tuner's input to the transmitter, the second tuner's input to the wattmeter and a dummy load. Then connect the tuner outputs together, using a ground strap between them if they have single wire outputs.

Set the second tuner arbitarily, and adjust the first tuner for 1:1 SWR at the transmitter. Now you can see how much loss there is at various knob settings, for the two tuners combined. When loss is expressed in dB, divide by two to find the loss per tuner (assuming they are identical units).

Experiment to find the settings that work well for your tuner. If it's a "three knob" type (TEE network, etc.) you'll probably find multiple combinations that produce a match. Select the one that gives the most power to the dummy load.

This method also will find the losses for RF transformers, baluns, etc. In fact, I learned it from a Fair-Rite application note for measuring broadband transformers.

Good luck!

The G5RV was designed for 20m and performs well there with a multi-lobed pattern. It also works pretty well on 80m and 40m and I have Smith Charts on my web page that show why. The series section transformer actually does some matching on 80m and 40m. But it is not an all-HF-band antenna as it is sometimes advertised to be.

That ain't no joke. Two totally different animals, day or night. And just because a certain antenna beats another one at a certain time or distance, doesn't mean it's more or just as efficient. I've had my 40m car mobile antenna dog my home dipole at longer distances at night. "Texas to Florida" Is the 40m mobile antenna more efficient? Not hardly...It's just radiating what little it has to offer at just the right angle for the path/distance, etc.
I'd like to see one of these whiz bang shorty 160m antennas compare to a full size 250 ft dipole at 200-300 mile high angle skip in the evening. I suspect the dipole would tear the "shorty" a new one. MK

88. Re: CAM?? Parallel dipoles for 80 m and 40 m?

Source record: 139630

I'm starting to get it now. Except I can't see where 88' is 1/2 wavelength for
80 m. 120' would be 1/2 wavelength on 80 m.
And 100' would be 3/4 wavelength on 40 m. Using 468/f =
1/2 dipole length in feet.

With your antenna... could you get a W2DU BALUN on the
TX end of your ladder line and then use about 50' of RG-8
into the house without screwing anything up?

This is all starting to make more sense when one views all
of the parts as a system.

I need information for an old antenna tuner and cannot find any info about it. I have a mfj versa tuner II. model number mfj-941 (not mfj-941e), just plain old 941. I guess it will be about 15 to 20 years old. The problem is that I want to get back on the air. I have a kw ts-520 and never operated it (don`tknow how) but have manual. Can I use this antenna tuner with that rig? I don`t know a whole lot and especially in how to operate the tuner. It also only has 1 needle and 2 lines (one is for swr and the other is for rf power. How am I supposed to know which line am I reading? And this is a hf tuner right? Has I said there`s nobody I can talk too so i`m winging it on my own and don`t have cash to spend. I taking xtra caution to make sure I don`t harm the tubes on my rig. Has for my antenna I don`t know yet but likely will build a 10 meter dipole for starters. Basicaly what I`m asking is what are the operating procedures for this tuner? I don`t have any experience except I used to run a radio shack 10 meter radio in my car with a mag mount. The radio died 10 years ago and I haven`t been on the air since, and now I`m being forced to break out my new 27 year old Kenwood and learn how to operate it along with this tuner I picked up at a swap meet back in 1988. I`m such a dunce. help. 73`s kyle

Hi,

here is another but new one!
I asked for the price, it varies very much with the retraction-high: The
more elements the higher the price.
Ex.: 40feet pneumatic extended, 30kg headload, unguyded, the price swings
between roundabout 1500 to 2500Euro.

Agreed...I built one once. It did well on 20. But on 75 it was marginal at best. When I replaced it with a Delta loop on 20 and a 1/2 wave center fed with mini-8 on 75 my signal reports nearly doubled.

For what its worth.

160 meters is a good frequency band for daytime testing. Low-angle radiation is closely related to ground wave radiation, taking into account earth conductivity. Field strength measurements from an EH may be all that is needed for comparison. FCC published curves with slight adjustment can be compared with EH data.

If comparison in real time is desired, a full 1/4-wave vertical over an excellent ground should be the standard of comparison.

The EH should not be located within 10-wavelengths of the 1/4-wave vertical, to avoid coupling.

Best regards, Richard Harrison, KB5WZI

You also have to be very careful when adding baluns to systems with
high common mode excitation.

The E-H antenna would fit that descripition perfectly. If you
actually INTENTIONALLY designed a system to excite the coax as much as
possible, it would look like an EH antenna configuration!!!!

Ted Hart and Steve call themselves liars at every turn.

One strong point is the theory Ted Hart and Steve put out. They say
they feed TWO terminals in phase quadrature, or at least in phase
quadrature between voltage and current (which means by definition the
system can not consume ANY power from the rig).

It is always, by definition, IMPOSSIBLE to build an antenna or any
other load with 90 degree phase shift between the two terminal
terminals when the antenna or load only has two-terminals. It would
also be electrically impossible to present a zero-reactance 50-ohm
feed into an electrically short radiator, when the voltage and current
are exactly 90-degrees out of phase. By definition, that is a PURE
reactance with zero power absorbed from the generator!!

Circuit law simply does NOT allow such a feed into two terminals.

Because of that, a third path must be involved in the feed system.
There has to be a third leg carrying considerable current, and that
leg could carry any ratio of power.

A W2DU style balun easily may NOT have enough impedance, even when
installed at a LOW differential mode impedance point, to reduce common
mode current or isolate the feedline! It is a somewhat common mistake
to assume a low differential mode impedance means the common mode
requiremenst are also easy. The two mode are NOT related at all, and
can have any impedance relationship. As a matter of fact, adding a
choke can *increase* common mode currents, decrease them, or have NO
effect at all in current levels despite the fact the cable is

radiating.With the actual way the system works in mind, we can see adding a choke.

Virtually all of the supporting measurements clearly indicate the people making the measurements, like the people offering the theory, just don't completely understand what they are doing. They are stumbling around in the dark, without any idea what t do. In order to make a good measurement, you have to understand the system and how the system and the measuring instruments or protocol works.

On the other hand people with an open mind who use the scientific approach, and who attempt to do things right and double check themselves, universally conclude the antenna does not work as claimed.

My 10 foot tall 160-meter mobile antenna, with about 1% efficiency, is
significantly STRONGER on groundwave at ten miles with 100 watts
applied than my dipole at 300 feet is when I apply 1500 watts to the
dipole!

That's true day or night on 160, BROADSIDE to the dipole.

The dipole actually beats the vertical off the ends of the dipole,
under the same conditions. But only when the dipole is fed with about
ten times the power as the mobile runs.

The highest efficiency normally appears when minimum inductance and maximum capacitance that permits matching the load is used.

The only exceptions come at the upper frequency limit of the tuner components.

> Or does that loss NOT EXIST after I tune it?
> This is really confusing me.
==========

I am not surprised at your confusion considering the nonsense which is plagiarised around the magazines, newsgroups and on the amateur chatter bands.

A tuner at the transmitter end of the line, where it usually is, has no effect whatsoever on the SWR on the transmission line. Neither can line loss be changed by anything you can do by adjusting the tuner.

Neither does your SWR meter indicate the SWR on the feedline. That is a very popular misconception.

But don't worry about it. Line loss on a 600-ohm line is small for very large SWRs. That is exactly why a 600-ohm line is chosen.

It is obvious that reflections and SWR on the line arise from the difference at the end of the line between the line impedance Zo the input impedance of the antenna. There is nothing which can be done about it at the transmitter end.

The purpose of the tuner is to transform the impedance seen looking into the feedline, whatever it might be, into the purely resistive 50 ohms required by the transmitter.
==========

> Also, is there something that I can change it from ladder line
> to coax right before it enters the house?
> Or does this defeat the whole purpose of using ladder line?

==========

It all depends on the length of coax which acts as a lump of capacitance across the end of the line. Too big a lump and the tuner is unable to tune it out without suffering a loss within itself.

To bring the 600 ohm line into the shack just bring the two wires close together for a few inches, with some additional insulation, and bring them through one relatively small hole in the window glass, window frame, or wall. Once inside the house you can continue with 450-ohm ladder line to

the tuner. Or put the tuner on the window ledge or conveniently near the window.

Once you have transformed down to 50 ohm coax electrically you can have it as long as you like. But it might be inconvenient to have to walk between transmitter and tuner when changing frequency and bands.

> And 100' would be 3/4 wavelength on 40 m. Using 468/f =
> 1/2 dipole length in feet.

Let's take 80m first. With a 130 ft dipole and 88 ft of 450 ohm ladder-line, my antenna *system* is resonant on 3.993 MHz. However, the dipole *length* of 130 ft is resonant on 3.6 MHz. The antenna is actually 0.555 wavelengths long on 3.993 MHz so the feedline has to be made shorter than 1/2 wavelength to make the antenna *system* resonant on 3.993 MHz. This is the principle of changing the length of the ladder-line in order to cause a dipole *system* to resonate on some other frequency besides the frequency of the resonant length of the dipole.

Consider a 1/2 wavelength dipole fed by 1/2 wavelength of ladder-line. It is resonant on one fundamental frequency. If you increase the frequency, the antenna becomes too long so the feedline has to be shortened to achieve system resonance at the new frequency. If you decrease the frequency, the antenna becomes too short so the feedline has to be lengthened to achieve system resonance at the new frequency. The feedline acts similar to a shorted stub. Check out the description of my all-HF-band antenna on my web page for more details.

For 40m, the 130 ft dipole is longer than one wavelength so the feedline has to be made shorter than 3/4 wavelength to bring the antenna system into resonance at about 7.2 MHz. And you left out velocity factor of the ladder-line in your calculation above. For 450 ohm ladder-line, the 1/2 wavelength formula is approximately 440/f.

> With your antenna... could you get a W2DU BALUN on the
> TX end of your ladder line and then use about 50' of RG-8
> into the house without screwing anything up?

Yes, as long as my ladder-line remains constant at 88 ft. 88 ft of 450 ohm ladder-line feeding my 130 ft dipole at about 30 ft height, puts a current maximum point (minimum resistance) at the balun/choke and any length of coax from there would be OK. But you cannot duplicate my results by simply copying my dimensions. Your antenna environment varies from mine and so also will your antenna system dimensions for the same results. In fact, you may not be able to find a single ladder-line length that will cause antenna system resonance simultaneously on 75m and 40m but, with a little help from your antenna tuner, you can come close enough. An antenna system that is resonant on 4.1 MHz and 6.9 MHz can easily be tuned with an antenna tuner on either band. Or you can choose to use a different length of ladder-line on each of the two

bands. Note that resonating my 130 ft dipole on 3.6 MHz requires a feedline length of about 120 ft but I don't work 3.6 MHz so I never need that long a length of feedline.

It'd make a good "dummy'. Mount it high and run RG58 to it-but don't
hook the dish end of the coax to anything, just let it float. Load the
coax shield as a random wire antenna vertically polarized. You won't
even have to worry about antenna insulators. Lay a 30-40 foot wire on
the ground in a flower bed etc. for the counterpoise.

I use a "spare" dish mounted on a discarded floor model electric fan
stand (which breaks down for compact storage) for portable satellite TV
when we travel.

Doubling is only 3dB. :-) With a well-designed G5RV the 75m results should
give only a slight S-unit edge to the 1/2WL CF. How much and what kind of
coax? Did you have a good choke at the coax/twinlead junction? Were both
antennas at the same height?

I am trying to recall....lets see I used 33' of 300 ohm line I think. As I recall it was a copy of the original G5RV. The one without any balun in it. And I think the horizontal part was 105'.

What I did was remove all the feed stuff and extend the length to 120' and fed with mini 8, which made it into a 75 meter half wave dipole.

I really don't recall the exact length of the line. 'CAM'. My main point was on 75 it didn't work all that well.

Tom W8JI wrote:
> The two mode are NOT related at all, and
> can have any impedance relationship.

Tom, if they have (as you say) any "relationship" at all then they are,
by root word definition, "related". Wouldn't it be better to say their
relationship is somewhat unpredictable instead of "NOT related"?

"NOT related" = no relationship

"any relationship" = unpredictably related (until measured)

I compared a symmetrical center fed dipole to an off-center-fed dipole.
I predicted that the common mode currents would be related to the
amount of unbalance in the differential feedpoint impedances. Just as
I predicted, the OCF dipole common mode current measured a magnitude
higher than the symmetrical CF dipole. If common mode conditions are
"NOT related" to differential mode conditions, how was I able to
predict the ballpark outcome of my measurements?

111. Fractal Wire Antennas

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-02 14:13:21 UTC
From: VE9SRB <srbest@att.net>
Message-ID: <5yiU8.288$Iu6.16963@bgtnsc04-news.ops.worldnet.att.net>
Source record: 139650

This is not intended to be a "debate", just a statement of opinion (or fact depending on your perspective). This is also very long - sorry. I won't post any other long statements on this subject.

The electromagnetic behavior and performance properties of a wire antenna are a function of the antenna's physical properties. These physical properties include the antenna's size (height, area, occupied volume, etc.), total wire length, geometry and wire diameter. If we conclude that the electromagnetic behavior and/or performance properties of an antenna are uniquely or primarily a function of one of these physical properties, we must also conclude that significantly modifying this one physical property will significantly modify the antenna's electromagnetic behavior and/or performance properties.

If we are to conclude that antennas having fractal geometry behave in a manner differently or better than antennas with a non-fractal or some arbitrary geometry, then we must fix all of the antenna's other physical properties (size, total wire length and wire diameter) and compare the electromagnetic behavior and performance properties of the fractal antenna with those of antennas having different geometries. This is something that none of the proponents of fractal geometry have done in the open literature. Not one. Let's consider this further.

1) Cohen, in a series of Communications Quarterly articles, published the performance properties of the Minkowski Island fractal loop antenna. He demonstrated that with increasing fractal iteration these antennas exhibit a lower resonant frequency than a Euclidean (square or rectangular) loop of the same size (occupied area). He also demonstrated that in some regions of low frequency, the Minkowski Island fractal loops exhibit a higher radiation resistance than the Euclidean loop of the same size. Cohen concluded that the electromagnetic behavior and relative performance properties of the Minkowski Island fractal loops are primarily a function of the loops' fractal geometry. It is significant to note that two physical parameters of the antenna change with increasing fractal iteration. One is the antenna's geometry and the other is the antenna's total wire length. While the performance data presented by Cohen is mostly accurate, his conclusion is scientifically flawed because he is varying two of the antenna's physical properties but concludes that the antenna's electromagnetic behavior is primarily a function of only one of these physical property - its fractal geometry.

To scientifically validate his hypothesis, Cohen would have to compare the electromagnetic behavior and performance properties of the Minkowski Island fractal loop with those of other geometry loops having the same size, total wire length and wire diameter. He did not do this. When we compare the

Minkowski Island loop with loops of differing geometries but otherwise having the same size, total wire length and wire diameter, it is evident that they exhibit very similar electromagnetic behavior and performance properties. In some cases, the arbitrarily shaped loops behave better than the fractal loop and in some cases, the fractal loop behaves better than the arbitrarily shaped loop. In all of this however, the most significant fact to note is the following: when the total wire length of the arbitrarily shaped loops is adjusted such that their resonant frequency matches that of the Minkowski Island fractal loop, they have virtually identical radiation resistance and bandwidth. The resonant behavior of these loops is primarily a function of the loop size with respect to the resonant wavelength and the resonant properties of these loops are essentially the same independent of the differences in loops' geometry and total wire length.

2) Puente's work on the Koch fractal monopole suffers from the same scientific flaws as Cohen's work on the Minkowski Island loops. Puente describes the behavior and performance properties of the Koch fractal monopole as a function of increasing fractal iteration (increasing total wire length) and demonstrates that, when compared to a Euclidean (straight) monopole of the same height, the Koch fractal monopoles exhibit lower resonant frequency and increased radiation resistance in some regions of low frequency. Puente even goes as far as claiming that the complex shape of the Koch fractal curve enhances its radiation properties. Again, it is significant to note that Puente did not bother to compare the performance of the Koch fractal monopole with another monopole of different geometry but otherwise having the same physical properties (height, total wire length and wire diameter). For example, if we compare the Koch fractal monopole with a simple meander line monopole and normal mode helix of the same height and total wire length, we see that these simple geometries exhibit significantly lower resonant frequency and higher radiation resistance at low frequencies. As a function of height and total wire length, these simple structures are more effective radiators. Two points are even more significant: a) when the wire length of the meander line and normal mode helix antennas is shortened (while maintaining the same height) such that their resonant frequency matches that of the Koch fractal, they exhibit virtually identical radiation resistance and bandwidth. The resonant behavior of these monopole structures is primarily a function of their height with respect to the resonant wavelength and is essentially the same independent of the differences in geometry and total wire length. b) below the small antenna limit (ka < 0.5, k = 2pi/WL and a is the radius of a sphere encompassing the maximum dimension of the antenna), the radiation resistance of all these antennas converges to that of a Euclidean monopole of the same height.

3) One of the most profound and yet totally unsubstantiated conclusions regarding fractal antennas is that stated by Vinoy et al in an article titled "Hilbert Curve Fractal Antenna: A Small Resonant Antenna for VHF/UHF Applications" published in Microwave and Optical Technology Letters. In this article the authors claim "A fourth iterated fractal Hilbert curve geometry inscribed in a square of 7 cm is shown to result in a resonant frequency of 267 MHz, which is much lower than any other resonant antenna of similar size." How many other resonant antennas of the same size did they compare

with the Hilbert curve antenna? - zero, no even one. I fabricated a simple meander line antenna of the same size and total wire length as the Hilbert curve and it had a resonant frequency of 154 MHz.

The trend in the study of fractal wire antennas is to compare the fractal antenna with a simple Euclidean antenna and jump to a range of conclusions that are, for the most part, unsubstantiated. Comparing the fractal antennas with other geometry antennas of the same size, wire length and wire diameter provides clear evidence of this. It should be inherently obvious that increasing the wire length in a fixed size antenna lowers its resonant frequency and increases its radiation resistance over some range of low frequencies as compared to a straight Euclidean antenna. This behavior is simply not unique to antennas with fractal geometry. There is no inherent or unique benefit to a fractal geometry antenna compared to an antenna with virtually any other geometry. Fractal wire antennas do not behave in a unique manner nor do they behave in a manner significantly different than antennas with other geometries. This is especially true when the antennas are made to be resonant at the same frequency. It is interesting to note however, that in most cases, a self-similar fractal geometry is generally the least effective geometry in terms of lowering resonant frequency as a function of total wire length.

If the discussion turns to the concept that all bent wire geometries are "fractal" then the discussion gets even more ridiculous - we have assigned a new term to bent wire geometries but have learned nothing new about the fundamental behavior of antennas.

Perhaps the lack of a choke caused your feedline to radiate in undesirable
directions while preventing some of your RF from reaching the dipole.

Tom, W8JI wrote:
"The two mode are NOT related at all, and can have any impedance relationship."

There he goes again!

When changing the voltage across a transmission line changes the current the line conductors carry as if in paralllel, the differential-mode is related to the common-mode.

An example to show what common-mode and differential-mode are is in order. You can use any a-c frequency fron audio to microwave in imagining this example. You may even use d-c for the common-mode signal, as is frequently done for control on an audio circuit.

Take a parallel-wire line and terminate it with center-tapped transformer windings at both ends.

Assume perfect balance in the line and transformers. We can use additional windings on the line transformers to input and output on the line.

Voltage between the transformer center-taps and ground is zero. That is because the circuit is balanced. The voltage between center taps is zero. The entire circuit is really a bridge circuit.

We can place a signal between one center-tap and ground and recover that signal between the other center-tap and ground. This is a common-mode signal because it is carried by both wires in the transmission-line as if they were parallel conductors using a ground connection to complete the circuit.

The common-mode signal using the center-taps of the transformers does not mix with the wire-to-wire differential-mode signal because the differential-mode signal is balanced and there is no "mutual impedance" shared by the signals. Without a mutual impedance, one signal does not become a "function" of the other signal. That is, imposing a change on one signal does not affect the other signal.

Unbalance the system, and the signals mix. One becomes a function of the other. When you change the differential-mode voltage it affects the common-mode voltage.

This is the same cause and effect we have been discussing with transmission-line imbalance or antenna imbalance, and r-f returning from the antenna on the coax exterior, or returning on parallel-line wires as a common-mode signal to the shack. Imbalance provides a mutual

impedance.

Tom just does know what he is talking about.

Best regards, Richard Harrison, KB5WZI

Kyle,

I'll try to help, but this might be a little difficult..

First piece of advice: Ignore the arse-hole G3 who has
already replied and displayed his own ignorance and
arrogance. Hiding behind a keyboard brings out the
ass in all of us, but some are more severely affected!

That being said, lets try and figure this out, OK?

kyle <CB750FSuperSpor@webtv.net> wrote in message ...
> I need information for an old antenna tuner and cannot find any info
> about it. I have a mfj versa tuner II. model number mfj-941 (not
> mfj-941e), just plain old 941. I guess it will be about 15 to 20 years
> old.

Try to find a manual. Possibly through the MFJ company. See if there
is any help available on-line. In general, this is an HF antenna tuner,
without a dummy load. That is important, because with the TS-520S
you will want to tune the rig into the dummy load before you attempt to
tune the antenna. So, I would first acquire a dummy load of some sort.

The problem is that I want to get back on the air. I have a kw
> ts-520 and never operated it (don`tknow how) but have manual. Can I use
> this antenna tuner with that rig?

Yes.

I don`t know a whole lot and
> especially in how to operate the tuner. It also only has 1 needle and 2
> lines (one is for swr and the other is for rf power. How am I supposed
> to know which line am I reading?

Usually there is switch on the tuner labeled something like
"Forward/Reflected"
or "Power/SWR" or something similar. Since the meter only has one needle we
need to switch between power reading and SWR reading. Now, I have a 941C
which
must be very similar to your tuner, and it has a button labeled FWD/REF and
a
knob that is labeled SENS/Power. Assuming that you have an antenna attached,
what you do is turn the knob all the way to the right, which is the lowest
power setting.
Put the FWD/REF switch in the FWD position.Then feed in a little power, just
enough to bring the needle all the way to the right on the bottom, (SWR)
scale.

Then switch to the REF position. The meter is now reading SWR. You can use the tuner just for SWR readings or you can use it as an antenna tuner.

Realistically, You are better served just using the SWR function for now. A ten meter dipole is so easy to build and so small that a tuner is not needed.

Really! I would venture to sat that is true all the way down to 40 meters, where
a half-wave dipole is still only about 66 ft long!

Not to be sarcastic or anything, Kyle, but now is the time to begin reading about radio. Some reference works to consider:

1. "ARRL Handbook", any year.

2. "ARRL Antenna Manual", any year.

3. "Now You're Talking" also from ARRL pubs and available at Radio Shack.

4. "ARRL Operating Manual"

All of these publications are available through the ARRL, but most of them carry a premium price tag, with the possible exception of the "Now You're Talking", which as mentioned before, is available at Radio Shacks nationwide. Some of the ARRL publications may be in your local library.

Good luck, and don't let the buttheads, like the aforementioned G3 get you down. For some reason. hams on the Internet can be some of the most arrogant, assholes on the face of the planet. The funny thing is that just the opposite is generally true of the hams who you will meet on the air.

I suppose that the Internet just brings out the best in some people!

73, Gary WG7X

I would also add, since you live in L.A. and they have a good public library system there, you should go to the central branch of the library and look at the books they have on amateur radio, and they also probably have subscriptions to QST and CQ magazines. When I was a kid, the Dallas Public Library, downtown branch, had all that stuff, and it was a cheap way to get up to speed on ham radio technical stuff.

Hi Dick

Thanks for the compliment!

Seeing your post set me back for a second. The particular apartment I lived in was owned by Ray Hughes (now deceased) his sons name was Richard.

When I opened the post I expected to see a comment about all the ground radials and a small part of a dipole I left behind when I moved. Then I thought to myself, that was over 20 years ago, the statute of limitations surely has run out, hi hi.....

One of the houses I moved into, the subdivision did not have very stringent CCRs and I put up a beam on a short 30 foot tower. They made me take it down. Even though there were 3 other hams in the same subdivision. A fourth moved in next door to me and put up a 75 foot tower and a couple of massive beams. I put my little 30 footer back up again and again was told (by certified letter) to take it down. I was a longtime member of the ARRL and got them involved in the issue. They came out full guns for the new ham, and he got to keep his antenna up by special permission of the subdivision trustees. Me, well my antenna had to come back down and they could care less about my situation. I have not been a member of the ARRL since!

Somewhere in the interesting explanation
of how this antenna works, the GAP
web site claims an "antenna resistance"
of 2.8 ohms on 20 meters. This is fairly
close to the 3.5 ohms feedpoint impedance
Sevick claimed for his short 40 meter
vertical as written up in some of the
ARRL antenna books. How do these
fellows feed these antennas, and how do
they know how much of the energy is radiated and how much is converted to heat?
(Sevick claimed high efficiency for his antenna, too.)

CAM, W5DXP wrote:
"Gamma match."

Page 26-9 of the 19th edition of the ARRL Antenna Book goes into the gamma match. It works with a grounded tower as if the dipole element shown in Fig 10 were the earth.

A sloping wire can be used between capacitor "C" and the point found up the tower which matches your coax. It`s been used by some medium wave broadcasters with single towers. Radiation from the slant-wire can be troublesome to maintenance of a directional array pattern. Shunt-feed also requires cut-and-try because calculations for the feed-point on the tower are inexact.

I think I understand Tom's strategy here. If he uses "related" enough times in his postings, he may get Webster's to add a new meaning to the word.

>Not one.

Steve makes a point that is fundamental to measurement. It is called
the reduction of variables. He has named several above, which, if
they were not fixed nor accounted for, would lead to serious
distortions in the outcomes and analysis of measurements.

>
>the electromagnetic behavior and relative performance properties of the
>Minkowski Island fractal loops are primarily a function of the loops'
>fractal geometry. It is significant to note that two physical parameters of

>

These are the two major and obvious considerations to base comparisons
on given that geometry relates to launch characteristics and wire
length relates to drivepoint characteristics (both being
generalizations, it should be obvious that they contribute to each
other as well).

Within the scope of my work, I have explicitly designed my models to
these benchmarks. In my work I refer to them as either being Constant
Height surveys or Constant Wire surveys.

>
>To scientifically validate his hypothesis, Cohen would have to compare the
>electromagnetic behavior and performance properties of the Minkowski Island

>fractal loop with those of other geometry loops having the same size, total
>wire length and wire diameter. He did not do this.

I have purposely avoided loops as a class as this was yet another
variable that offered very little new insight above and beyond study
of the humble monopole. This is not to say I abandoned the field as I
have a number of loops at my pages. I included them both for the sake
of comparison (limited albeit) and for novelty.

>When we compare the
>Minkowski Island loop with loops of differing geometries but otherwise
>having the same size, total wire length and wire diameter, it is evident
>that they exhibit very similar electromagnetic behavior and performance
>properties.

I can say that by and large this is true, however there is a continuum
of variation that is driven by one variable: the discontinuity
presented to the element by a kink to enforce an arbitrary shape.

>when the total wire length of the arbitrarily
>shaped loops is adjusted such that their resonant frequency matches that of
>the Minkowski Island fractal loop, they have virtually identical radiation
>resistance and bandwidth.

When the physical dimension of the overall antenna is much less than a
wavelength (the stated application for fractals), differences are
minuscule. This goes beyond the exclusive statement above to include
the entire class of fractals compared to themselves or standard
structures.

>The resonant behavior of these loops is primarily
>a function of the loop size with respect to the resonant wavelength and the
>resonant properties of these loops are essentially the same independent of
>the differences in loops' geometry and total wire length.
>

I would note that fractal loops and fractal dipoles are very different
beasts in that closing the ends presents the user with fewer
resonances. When we do get into variation in the number of resonances
in comparison to other structures, it is clear that a fractal
compresses more into its design. This is not a characteristic unique
to the fractal however and neither does the fractal present itself as
the optimum form.

>
>when compared to a Euclidean (straight)
>monopole of the same height, the Koch fractal monopoles exhibit lower
>resonant frequency and increased radiation resistance in some regions of low
>frequency.
>

This reveals the poverty of the "belief circle" scientists where I
have five times the work (on just one page) revealed for side-by-side

comparison. I would offer that nearly everyone here is unaware that there is a Quadratic form of the Koch and a Triadic form - they are quite different. I would also note that the fractal "belief circle" seems to exist on very, very few models outside of the Koch (and begs the question why they insist on the generic term fractal antenna when attention rarely swerves from koch antennas).

One good answer to that last rhetorical question would be that fractal forms abound in very poor examples. Our "belief circle" scientists would be forced to confront contradictions to their carefully crafted insights into a new form of fractal electromagnetics. As Scientific American notes about these charlatans:

>>
>>5. Has anyone gone out of the way to disprove the claim, or has only
>>supportive evidence been sought?
>>This is the confirmation bias, or the tendency to seek confirmatory
>>evidence and to reject or ignore disconfirmatory evidence.
>>

>Again, it is
>significant to note that Puente did not bother to compare the performance of
>the Koch fractal monopole with another monopole of different geometry but
>otherwise having the same physical properties (height, total wire length and
>wire diameter).
>

This statement attends the poor quality of science practiced. To me, it underlines an utter disregard and contempt for their audience.

>
>If the discussion turns to the concept that all bent wire geometries are
>"fractal" then the discussion gets even more ridiculous - we have assigned a
>new term to bent wire geometries but have learned nothing new about the
>fundamental behavior of antennas.
>
>
>Steve VE9SRB
>

Hi Steve,

The joke of this is that four or five years ago I found that any fractal advantage was a mis-credit to deflect attention away from the simple matter of putting a kink in a wire. Steve, your random bent wires that won the Fractal Challenge some years back supported this observation.

As to the culture of the fractal "belief circle." That group steadfastly moves around the periphery of their goal so as to not attain its mediocre pay-off. As long as the goal remains "elusive," the magicians can mumble oaths and insist that the stars be in alignment before the next test (the Italian Gambit).

My studies have cut to the heart of the matter and the data reveals that as a class, fractals, by the nature of the variation of their geometry, presents a continuum of characteristics that can be ordered rationally against simple correlatives. There is not much advantage to be gained by this except a certain intellectual satisfaction. However, this does not sell patent medicine, and knowing the ingredients of doctor hokum's fractal-elixir does not reveal a cure.

That`s a knee slapper!

I am as skeptical as Tom of the EH antenna. I hope the promoters have a new scientific discovery despite my doubt. I think Tom hopes they don`t. I don`t mind revising my decisions on right, wrong, and the way things work, to fit new information.

Just as the promoters can`t prove anything with baloney, it won`t be disproved with baloney either.

Best regards, Richard Harrison, KB5WZI

Dave,
I think what the man is trying to say is that
while the G5RV is a nice 20 meter antenna, it isn't
the 'miracle', all-band, antenna it's tauted to be.
Like most 'stories', it's abilities tend to get
bigger the more often the 'story' is told. This is
a fairly common advertising ploy (ploy = lie). I
also think he may have been saying "TANSTAAFL"...
'Doc

PS - "TANSTAAFL" means, "There ain't no such thing as
a free lunch", which is true for everything from
radio to rat traps.

AD9E,
In effect, yes. It can be used on any frequency.
If the length of the wire has some meaningful relation
to the frequency used (1/4, 1/2, 1/? wave), your signal
will be 'better'. As to the power it can take, it can
handle any power level the 'cantenna' can stand, for
the same length of time.
Will this make a 'good' antenna? No. But it will
work in that it presents a 'good' match to your transmitter
allowing full power output. Some may rememeber a device
sold in the early '80's(?), by a company called "K-Comm",
"Maxx-Com" (can't remember the name, rats). It was a
'potted' device said to provide a good match to almost
any length wire. When X-rayed, it was only a 50 ohm
resistor with a connection for a wire. It worked very
well for some people, and they were happy with it...

It does matter on some designs, where a series cap is used before the
gas discharge tube. PolyPhasors are clearly marked "antenna"
and "equipment". I'd drop MFJ service a line and ask it makes a
difference on the MFJ270 device.

This certainly isn't a defense of EH antennas. Note that Tom's statement doesn't apply only to the EH antennas but to antennas in general. What I wonder is how he can predict and cure common mode problems if they are "NOT related" to differential mode conditions? Wouldn't being "NOT related" to differential mode conditions make them completely unpredictable and beyond the reach of human knowledge?

The 3:1 SWR bandwidth on 80m is about 160 kHz and about 290 kHz
on 40m, i.e. virtually the entire band on 40m. The 'Q' of the
antenna appears to be about 40. 'Q' = BW/f

Hi Cecil,

This has gone on much too long for me to have followed to the matter
of punctuation and fly-specs, but it seems to me that what is being
argued is not so much relations of causes as relations of effects.
This group has always presented a problem of being able to separate
dependent variables from independent variables.

StarGazer wrote:
"What is the Bandwidth on 80 and 40 that doesn`t go above 3:1 SWR---?"

A complete formula for antenna Q appears on page 2-5 of the 19th edition of the ARRL Antenna Book:
Q = fo (deltaX) / 2Ro (delta freq.)

Notice that Q is proportional to the operating frequency divided by the bandwidth.

Not much to figure. A horizontal dipole typically outperforms an equal-sized vertical dipole over real ground by several dB (see ARRL Antenna Book, chapter on the effects of ground).

From: Bads <pete@g0wxj.freeserve.co.uk>
Message-ID: <aft7pubpr1@news8.svr.pol.co.uk>
Source record: 139583

Hi Chaps,
I have a CP5 vertical that has been out of commission for some time now. Upon shoving some RF up it, it was apparent there was a fault with it, high SWR and not wanting to resonate anywhere.

I suspect it is one of the 2 feed capacitors that have gone, can't see anything written on them though. Anyone have any ideas what values they are or if you have had the same problem. This antenna is so simple in construction that I am sure it's the caps.

All help appreciated

Pete

you only have to compensate if you are doing something very critical, and mostly only at vhf/uhf frequencies. at hf the loss is so low that the small mismatch created by a 50 to 75 ohm transition can be ignored.

"Not related" means no relations of causes and no relations of effects.
Unknown relations or unpredictable relations would be reasonably accurate.
"Not related" is just downright false. I can read Morse code by watching
my common mode meter during the transmission of CW. How can that be
"NOT related"?

147. FOR SALE - ROHN 45G TOWER SECTIONS

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-02 23:50:53 UTC
From: wrhood@exis.net
Message-ID: <3d223c05.1954436@news.exis.net>
Source record: 139589

Ninety feet of Rohn 45G tower sections (9 each 10 foot straight
sections) ready for pickup or delivery within 100 miles of Chesapeake,
Virginia. The galvanized coating has some rusting on only about
15-20% of surface; a gallon of "Rust-Stop" and a gallon of paint and
the sections would be like new. New value of $1,469.70 plus freight;
available for less than 25% of new, Pickup priced at $350.00 in
southeast Virginia, Chesapeake. Presently in trailer ready for
delivery and will haul up to 100 miles for $400.00. (Might consider
$.50 a mile after 100 miles if within reason), Cash deal, if payment
by check, check must clear bank before delivery.
Call (757)487-0357 or e-mail <wrhood@exis.net>

The mail brought March/April QEX and I've been through your article
a couple of times. Did your non-selfsimilar bent wire antennas have to
be symmetrical in order for there to be a valid comparison with the
fractal antenna?

Hi Richard,
Sorry it took so long to respond - sometimes work gets in the way.

Gee, I hope another nail in the coffin doesn't hurt (sorry about the
illusion to death). I did want to state the obvious in pointing out
that the degenerate bow tie violates the following claim made during
yet another challenge several years ago:

> I am stating, without any sense of ambiguity or doubt, that frequency
> independent antennas are necessarily both self similar and origin symmetric
> (in a planar projection).

> Every single one.

> Self similarity and origin symmetry are the necessary and sufficient
> conditions for frequency indepndence.

Anyone interested in this previous challenge can find the thread by
doing a Google search on "fractal indepndence ambiguity"
Thanks for re-posting that PDF. vy 73,

Richard,

Current is related to voltage and resistance by formula. Capacitive reactance is related to frequency by formula, as is inductance.

All of these things have well-defined rules or laws, and the people who helped define them like Faraday or Ohm or Henry are honored.

Please give me the formula that shows the direct relationship between common mode and differential mode impedances that universally works in all systems ...so we can call it Harrison's Law.

You should be able to prove they are related if YOU know what you are talking about by giving a formula that always shows the relationship between them.

If you do that, then I will retract my statement and agree that I am the one who does not know what he is talking about.

If you can not do that, then I assume you are all hot air and insults without any real knowledge except bafflegab.

Getting ready to dig the concrete base for my new tower and plan to run a 1 1/2 inch PVC pipe from my shack to my tower about 30' away and up through the concrete base. This pipe is big enough to carry several coax lines plus the rotor cable, so is there any reason I would want to run a separate pipe for anything else? I've never had a problem running the coax and rotor cable next to each other. The reason I ask is because I see photos of a tower installation on the texas towers website with two PVC conduits coming up through the concrete base.

>my common mode meter during the transmission of CW. How can that be
>"NOT related"?

Frankly Cecil, that does not prove anything.

They come from the same source power source, so naturally when that
source is removed they both disappear. But factually, the common mode
impedance can be anything compared to the differential mode impedance,
they have no fixed ratio or relationship that universilly relates them

While you might not like HOW I say that, you and Harrison (who makes
many large gaffs of his own) going out of you way to follow me around
and insult me does not help anyone learn anything.

It is childish (or more correctly Chippish) to spend all of your time
trying to get revenge because you failed to understand that moving a
balun in a floating network does nothing to relieve common mode stress
on the balun, or to improve system balance.

Let it go Cecil, and move on!

Let me give you an example, and tell me what flaw you see in this.

The rate I breath is not related to the rate you breath.

Just because the relationship is unknown or difficult to determine
doesn't mean that no relationship exists. Out of the following
possibilities, (B) seems to be the obvious answer.

A. Not related
B. Related but unpredictable
C. Related by a rigid formula

You are saying because (C) is not the answer then (A) must be the
answer. That's simply not true. The relationship obviously exists.
Nobody said it is a formula relationship. I don't know about your
system but with mine, the common mode current meter reading seems to
be very related to my Morse code during a CW QSO. Key down = common
mode. Key up = no common mode. That's pretty related, Tom.

> You should be able to prove they are related if YOU know what you are
> talking about by giving a formula that always shows the relationship
> between them.

They are phase locked, Tom, and you can see it on a dual trace scope.
That proves they are related and that your statement is false. In any
particular antenna system, the differential current can be measured and
the common mode current can be measured at a point. The magnitude/phase
relationship between them at that point will not drift willy nilly all
over the place as you seem to be suggesting.

Your concept that unpredictable and unmeasured things must necessarily
be unrelated is a very strange one.

Please supply the argument that the lack of a formula proves they are
NOT related, oh omniscient one. :-) Between "NOT related" and "formula
related", there is a very large middle ground that you are completely
missing - related but unpredictable, related but not measured ...

When you say they are "NOT related" you are saying that they are NOT
"connected by reason of an established or discoverable relation."
I submit your statement is false and anyone who wants to discover
the relation between their differential conditions and common mode
conditions has only to measure them like I did.

Decoding Morse code by watching the common mode current meter doesn't prove a relationship between common mode and differential mode??????
Tom, the differential power meter and the common mode current meter are perfectly synchronized.

> They come from the same source power source, so naturally when that
> source is removed they both disappear.

You have just admitted that they are related because they come from the same power source. They are so closely related that they are phase locked. Face it, Tom, the statement that you are defending is blatantly false.

> But factually, the common mode
> impedance can be anything compared to the differential mode impedance,
> they have no fixed ratio or relationship that universilly relates them

They are what they are and can't be anything else unless something is changed. Anyone who wants to can measure the relationship between them and they will retain that relationship as long as nothing is changed. Nobody says they have a fixed ratio. What is it about related but unpredictable or related but unmeasured that you don't understand?

> While you might not like HOW I say that, you and Harrison (who makes
> many large gaffs of his own) going out of you way to follow me around
> and insult me does not help anyone learn anything.

You are making false statements, Tom. You could easily be misleading a newcomer. Why should you get a waiver for your false statements? Stop making false statements and Richard and I will stop following you around. Deal?

> It is childish (or more correctly Chippish) to spend all of your time
> trying to get revenge because you failed to understand that moving a

Can't win this argument so you revert back to one you already won?

I admitted my mistake like a man and apologized. What is childish is to get caught in a falsehood and then try to weasel your way out of it by calling other people names. Fess up, Tom, you are wrong! How in the world can phase-locked signals supplied from a common power source be "NOT related"? To maintain such in the face of reality is extremely childish.

Subject: Re: Common-Mode Currents VS Loads
Newsgroups: rec.radio.amateur.antenna
Date: 2001-10-06 [06 Oct 2001] 15:58:56 PST
...
Has anyone double-checked to ensure that this isn't all just a simple misunderstanding ? Cecil restated his hypothesis fairly clearly the other day. I thought that I detected a glimmer of sunshine getting through between the two seemingly opposite positions... It seemed that Cecil was stating "A" was true, and everyone else was saying that "B" wasn't true (or was it vice versa?). The words "impedance" and "currents" were getting all mixed-up in the shouting. This sort of question shouldn't require any experimentation in the year 2001. It simply requires careful listening and understanding of the opposite argument and then a single well-aimed shot will deflate the whole thing. It really smells like a misunderstanding.

Best wishes.

Hello

This is what I actually think is the problem. Why, well when I lined the antenna 90 deg off the actually bearing to the tower it is facing a larger mountain. What I pickup is what I think is a bank shot from the main tower, this will also explain why there is such a big difference in reception quality (different channels bounce differently).

I have not yet tried to dampen the signal as the other messages suggested. Been buried in work so I have to postspone that to the 4:th July.

Cheers Olaf

R = E / I

Mutual impedance has magnitude and phase angle as we are considering voltage induced in one conductor produced by current in another, and the cobductors are separated in space. But, a complex quantity is the general case for any impedance.

Mutual impedance is defined as the ratio of induced voltage in conductor 2 to the current in conductor 1. (It`s reciprocal and works in either direction)

This ratio conforms to Ohm`s law. Double the current in conductor 1, and the voltage induced in conductor 2 also doubles because the physical and electrical characteristics in the situation of the conductors is assumed to be fixed, at least at a particular instant, and the ratio is constant. Something may be shaking the wires, so mutual impedance like any other impedance can change.

Mutual impedance is another name for coupling between antennas, wires, or other circuits. Mutual impedance is the word we usually assign numbers to.

In antennas and transmission lines, we are more likely to measure mutual impedance than compute it, but mutual impedance can be calculated using conventional network theory and analysis. Terman says in his antenna chapter:
"The actual details of the calculation are too involved to be presented here but can be found in the literature, together with formulas for many practical cases." Terman lists some references in the footnotes. The names are familiar to me for they are the texts I used when I studied such things a half century ago.

Mutual impedance between wires in space is just as valid as the mutual inductance between the primary and secondary of a transformer. Mutual impedance between wires has about the same purpose as the transformer`s mutual inductance. These are the names we assign numbers to to quantify the coupling.

Tom says I should prove common-mode is related to differential-mode.

OK. I just turned-off my differential-mode and my common-mode went away. It is repeatable every time and everyone else has the same experience. QED!

Best regards, Richard Harrison, KB5WZI

Tom, W8JI wrote:
"Please give me the formula that shows the direct relationship between commen mode and differential mode that universally works."

It is exactly the same as any impedance ratio. Say for example in a familiar situation, you have 9V rms across a loudspeaker and 1.11 amps through the load. By Ohm`s law the impedance is 8 ohms. You find 158V rms across the output transformer primary and 63 ma through the primary. The primary impedance is 2500 ohms. The impedance ratio of the transformer is 313.
The turns ratio, extraneous to our discussion, is 17.6 just as a matter of interest to some.

Same thing can be done with Differential-mode and common-mode signals. Measure their impedances by the voltmeter-ammeter method, then divide the common-mode impedance by the differential-mode impedance, if that is the way you would like ratio expressed. It works every time. I`ve done such measurements hanging sampling loops from wires etc. It works. The ratios obtained this way are just as good as any of similar circumstances.

Best regards, Richard Harrison, KB5WZI

"Please give me the formula---."

Mutual impedances can be measured and calculated. It takes more than an Ohmmeter.

The mutual impedance in a broadcast directional array is measured with an r-f bridge. B. Whitfield Griffith, Jr. gives an example in "Radio-Electronic Fundamentals". He gives 4 steps to measure mutual impedance between towers A and B.

1. Measure the impedance seen at the base of tower B with tower A open-circuited.
Call this ZB = RB + jXB
2. Measure the impedance seen at the base of tower A with tower B open-circuited.
Call this ZA = RA + jXA
3. Measure the impedance seen at the base of tower A with tower B connected to ground through a reactance equal to -XB, that is with tower B series resonated,
Call this ZC = RC + jXC
4. The mutual impedance between tower A and tower B may be referred to as ZAB and will be given by the following:
ZAB = sq. rt. RB(ZA-ZC)

Mutual impedance is the coupling between the towers and is a measure of the volts that appear in one tower as a result of current in the other. The ratio of volts to amps is complex in the general case but is expressed in Ohms. So, we are likely to have a current on an angle with the voltage with this impedance.

Best regards, Richard Harrison, KB5WZI

you know something,
this has to be the first real logically thought out rebuttle of the
"fractal antenna" hype that I have ever whitnessed.

In following up and reading additional sources (some of which were
provided herein), I've found that "fractal antenna" research is still
theoretical at best. Any so-called fractal antennas in real life are
either by absolute luck that they work, or are resonant elsewhere and the
only reason they would work on the band they were supposedly designed for
is a result of "multiple resonent points" within the antenna structure.

still, it is nice to see a reasonably thought out conclusion based on
real science, not snake oil!

Oh I see. They are related, it's just that you can NOT describe HOW
they are related since they are related in "an unpredictable manner".

So it isn't like the sun and moon and star's orbit are related in time
or position, and not at all like how current is related to voltage
through an inductor, capacitor, or resistor.

It's like the relationship Jennifer Lopez is having with you right now
as we speak, or like the well-documented relationship between the
position of stars when we are born to our personalities.

As in those examples, common mode and differetial mode impedances are
related in a random way where they can have any relationship at all to
each other, but according to you and Harrison it IS a relationship
because there might through random circumstance be a case where two
things happen at the same time, like stepping on a crack and breaking
moma's back.

Sort of like the relationship we have seen demonstrated between
showing common sense and giving an answer, isn't it?

I can't wait for Harrion's baffelgab on this topic, since I am the one
who doesn't know anything according to him.

Ahh, so that is the Harrison bafflegab.

>Mutual impedance has magnitude and phase angle as we are considering
>voltage induced in one conductor produced by current in another, and the
>cobductors are separated in space. But, a complex quantity is the
>general case for any impedance.

So you are saying Ohm's law is the formula for determining mutual
coupling between common mode and differential mode impedances.

Amazing answer. I would have picked E=MC^2, if I wanted to snow people
with yellow snow.

>Mutual impedance is defined as the ratio of induced voltage in conductor
>2 to the current in conductor 1. (It`s reciprocal and works in either
>direction)

Where can I find that definition?

>This ratio conforms to Ohm`s law. Double the current in conductor 1, and
>the voltage induced in conductor 2 also doubles because the physical and
>electrical characteristics in the situation of the conductors is assumed
>to be fixed, at least at a particular instant, and the ratio is
>constant. Something may be shaking the wires, so mutual impedance like
>any other impedance can change.

Ahh, so it a relationship like Cecils where the relationship can
randomly change to anything but you consider it a relationship because
each part of the system follows Ohms law, which is the law of mutual
coupling.

VERY interesting perspective, I'd bet we won't find that in any books!

>OK. I just turned-off my differential-mode and my common-mode went away.
>It is repeatable every time and everyone else has the same experience.
>QED!

I just read your post, and chuckled. That proves the relationship
between your thinking and my laughing. So far it is repeatable, and

the formula for mutal coupling is R=E/I.

The patent shows an off-center feed with no common-mode choke. Can't see what would prevent the feedline from radiating a lot. If 10 Ohms was measured at the feedpoint of an antenna that models around 2, one is left to ponder where the other 8 Ohms came from? One is also left to ponder how that adds up to nearly 100-percent effriciency? Little comparrison between Jerry's experiments and this design.

> Oh I see. They are related, it's just that you can NOT describe HOW
> they are related since they are related in "an unpredictable manner".

I can measure how they are related. Just because I am ignorant of how they are related doesn't mean that they are "NOT related". Your and my ignorance doesn't dictate reality. You obviously believe in primacy of consciousness rather than primacy of existence. Therefore, your knowledge is in control of the universe. That is a common mistake that prima donnas make.

Is the relationship between common mode current and differential mode current unknowable? Of course not! It can be measured and will keep that relationship as long as nothing is changed. Your assertion that two phase locked signals that share a common power source are "NOT related" is not only false but silly in the extreme and getting sillier by the day as you defend such a mistaken assertion.

> So it isn't like the sun and moon and star's orbit are related in time
> or position, and not at all like how current is related to voltage
> through an inductor, capacitor, or resistor.

Yes, it is exactly like the sun and moon and star's orbit are related in time or position. All those things were unpredictable. We didn't know how they were related until we *measured* them. There is no predictable reason why the earth is related to the sun in the way it is so we *measured* it to find out. Do you really think man has always known that the solar year is 365.25 days? Nope, we only knew that after *measuring* it. There is no formula for predicting the rotation of the earth in advance. It is what it is.

The same thing holds true for the relationship between differential conditions and common mode conditions. They are what they are. We can always measure those relationships and like the sun, moon, and earth, once they are known, they will remain the same in magnitude and phase until something is changed. Just like the earth and the sun, we can *measure* how differential conditions are related to common mode conditions. Your ignorance of exactly how they are related

does not change reality. You say they are "NOT related" before you measure
them but somehow they become magically related after you measure them? Get real!

> It's like the relationship Jennifer Lopez is having with you right now
> as we speak, or like the well-documented relationship between the
> position of stars when we are born to our personalities.

OK Tom, exactly what is the relationship of the second planet of Alpha
Centauri Prime to its star? You would say there is no relationship
because you don't know what the relationship is. Does that make
you feel omnipotent or what? The second planet of Alpha Centauri Prime
is unrelated to its star just because you don't know what the
relationship is? Sounds like megalomania to me.

> As in those examples, common mode and differetial mode impedances are
> related in a random way where they can have any relationship at all to
> each other, but according to you and Harrison it IS a relationship
> because there might through random circumstance be a case where two
> things happen at the same time, like stepping on a crack and breaking
> moma's back.

Does the second planet of Alpha Centauri have a random relationship with
its star? With your lack of knowledge, you may experience it that way
but your ignorance does not control the universe. The relationship is
what it is and someday we may be able to measure that relationship.
Just because a relationship is unknown to you doesn't mean the
relationship is random. All it means is that you may be surprised
when you choose to alleviate your ignorance and measure it.

I just flipped a coin and you are ignorant of the outcome. Does
your ignorance of the outcome of my coin flip mean that it still
has an equal chance of being heads or tails? Nope, the result of
the coin flip is fixed in time. Your ignorance cannot change
history, reality, or the relationships existing in universe.

The relationship is not changing randomly second to second, Tom.
If nothing changes, the relationship doesn't change. The conditions
are measurable, knowable, phase-locked and stable as long as nothing
changes just like the relationship between the sun, moon, and earth.

That's all you need to prove they are related, Rick, sharing a generator in common. But on top of that, they are phase-locked. And on top of that, the relationship is measurable and knowable and will remain stable if nothing is changed. Tom knows that but is simply too stubborn to admit that he can make a mistake.

It is a decent vertical - but pretty useless on 80 mtrs. Not as good as my top fed inverted L - 51 feet on a side fed with ladder line to a 1:1 balun to a short peice of coax to a tuner. The L works 160-10 and cost a lot less but you do need a couple 60 foot tall trees to get the top section up.

You can check out the GAP reviews at www.eham.net . Of course, most people who just spent close to $400 for an antenna have nothing but good things to say. The website is referenced there also. Be sure to wear your hipboots. The hype is pretty deep.

>Hi
>Has anyone had any experience of the GAP Titam or Titan antenna.
>Also is there a manufacture web site.
>Regards
>Tony

Tony I have used the GAP TITAN for several years and very pleased with its performance on 80-10m. I have it tuned for 1-to-1 SWR in cw portion of bands on 40, 20, 17,15, 12 and 10m. 30m I have to settle for about 1.8-to-1.

Let me start by saying that I have just worked Ireland from near Seattle on 900 milliwatts with a 569 report.

All antennas are some sort of compromise. Most folks that speak badly of the GAP TITAN have little or no concept of LOBE PATTERNS. Being basically a vertical dipole it has low angle lobe patterns and does not do well for close in stations which require higher angles of radiation for more of a vertical bounce.

Many folks having problems generally can be traced to poor coax, poor coax fittings, or never set up the GAP properly initially.

My GAP is located in a cluster of tall pine trees, and ground mounted on the side of a hill. It performs very well on both QRP and QRO. I use NEW BUY-IT coax for a 100ft cable run

As an added feature it does tune up well on 6m and 2m although it is not advertised for these bands.

Take a look at
http://www.njqrp.org/data/gap.html
and
www.mellinger.com/wa0sxv/titandx.html

You do need to supplement this antenna with one with high angle lobe such as a low dipole or loop or even an inverted-L. By the way a 11m by 11m Inverted-L with 12--5m radials gives you both high and low angle lobe patterns and I have used it VERY successfully on 160-10m. It has compared favorably with the GAP and strongly recommend it also.

Go to www.gapantenna.com for mfgr info. Hope this helps

I was pretty disappointed in mine so I yanked off the feed line and ran
ladder line all the way back to the shack (the classic G5RV configuration)
to a 1:1 current balun to a short piece of coax to a tuner. I hung what was
left (102 feet of wire) in an inverted L fed at the top. Now I can tune
160-10 mtrs and the antenna works much better.

No doubt, the hype surrounding the commercialization of this simple antenna
would make old Louis spin in his grave.

Hi Harv,

The problem is really that this is like convincing a Numerologist
there are not lucky numbers or bad numbers that control our lives.
For every 10,000 examples you can give that they are unrelated, the
Numerologist will find an example that seems to have worked.

Let me ask a series of questions:

1.) If common mode impedance increases, does differential mode
impedance either increase or decrease?

2.) If differential mode voltage increases, does common mode current
ior voltage increase or decrease?

3.) Is common mode voltage or current always phased locked to
differential mode voltage or current?

4.) Do any of the three above always occur in systems able to support
both modes?

If the answer to any of the above is ever given as a simple yes, it
would be an incorrect answer.

Now comes the final question...

Can anyone define any type of relationship or interaction between
common mode and differential mode impedances in systems that always
occurs, and follows a rule or interaction between the two that always
occurrs?

The answer to that would be no, they can not.

With that in mind, why would anyone in his right mind object to saying
the two conditions are unrelated?

I think the answer relates to an earlier thread. Harrison and Cecil
told me I was "stupid" when I said moving a choke balun from the
output of a floating network tuner to the input was useless for
improving balance or reducing balun impedance requirements. In a few
dozen exchanges were proven wrong.

I think the REAL answer has nothing to do with common mode, but it has
a lot to do with common sense.

I've successfully ignored the mismatch on 3/4" Trilogy fused disk 75 ohm CATV hard line all the way up to 5 GHZ. If you are a real purist, coaxial transformers are available for specific frequencies (I tried them on 1296) but the difference between them and my home brew, copper fitting, connectors was negligible. You could also tune the antennas for lowest SWR with the 75 ohm cable in the tested system.

Basically, I agree with Dave....don't sweat it.

Let me see if I understand this. You state above:

1.) You can not tell me how they are related, but you measure what
appears to be a relationship in at least one system.

2.) The reason you can not give me an answer as to how they relate in
all systems is you are ignorant about how or why they are related.

3.) You say they are related, but in an "unpredictable manner".

Is that about it?

From: "R. Scott" <washingtonham@yahoo.com>
Message-ID: <3D230744.40861A48@yahoo.com>
Source record: 139484

Hello all (especially Cam)

I have an 75m dipole that I couldnt get to prune to 6 meters (14th harmonic) so I dropped a 6 meter dipole on it at 90 degree angles. Problem is I can only get it down to 2 to 1 swr at 52.500 and its very steep skirts jacks it way up at the band edges. I wonder what could be the problem (there is a metal mast in between the dipoles is that causing it and how would I cure it)

Thanks

Rick KF7QZ

I did exactly the same thing, at about the same distance. In retrospect, I strongly recommend using a larger PVC pipe. After you have a few cables (coax or other) in the 1.5 inch pipe, you will find it very difficult to pull another cable through it. (Of course, you will include a pull-cord in the pipe. (?)) The larger pipe is a little more hassle to bury, but it will be *much* better in the long run. I have had no problem with coax, rotor, and relay control cables in the same conduit.

> be symmetrical in order for there to be a valid comparison with the
> fractal antenna?
>

Hi Bill:

In order to maintain a fair or valid comparison, I needed to eliminate as many variables as possible. In addition to the size, total wire length and wire diameter, it was necessary to keep the feedpoint in approximately the same location relative to the outside dimensions of the antenna. Beyond that I only considered the antenna symmetry about the feedpoint as a matter of convenience for creating the NEC (EZNEC) file. As I stated in the paper, the symmetry will affect the radiation patterns, especially at the upper series resonance where the antenna becomes larger with respect to the operating wavelength and where geometry becomes more of a factor in determining the relative behavior of these antennas. In terms of radiation resistance and bandwidth at the lower resonance, I don't think that antenna symmetry, in and of itself (all other things being equal - especially feedpoint location), is remarkably significant. I would have to check to validate this opinion.

That said, however, it is significant to note that moving the antenna feedpoint along the antenna structure and thus creating an asymmetric antenna or a different symmetric antenna, will change the antenna's resonant frequency and resonant properties.

What is evident is that the electromagnetic properties of an antenna are determined by so many physical factors that isolating fractal geometry, in and of itself, as a special or unique subset in terms of determining antenna behavior or performance is naive.

Source record: 139486

Allen, KB7MBI, summed it up pretty well, but here's a couple of additional comments.

Yes, the GAP Titan is a decent all-band antenna. I didn't buy it expecting it would be a miracle antenna, just wanted something convenient without having to buy a tuner. If you don't have excessive perfomrance expectations, you'll really appreciate this antenna. I got everything I expected and wanted.

If you do get one, be sure to guy it as recommended in the instructions. A number of people have gripped about how flimsy it is. Well, yes it is, that's why it's so lightweight and easy to put up. But if you just attach a few nylon ropes, the thing will be very stable.

Lastly, it's fairly easy and fun to assemble. The instruction book does leave a bit to be desired, but the information is indeed there. I managed to overlook the step where I was supposed to add the extender tube to the 12 meter resonator. After checking the SWR and having this extra tube on my hands, I went back to the instructions and found my mistake, but I feel the instructions could have be a bit more clear.

I hope this helps. 73,

There's that "always" catch word again. Are all solar systems always exactly like ours? Of course not. Do all solar systems obey the laws of physics? Antenna systems are just as varied as solar systems and like solar systems, they all obey the laws of physics. Measurements can be taken to ascertain the relationships among the components existing in the system. You can plot differential current Vs common-mode current for any measured antenna system. The plot will remain valid until something is changed.

> If the answer to any of the above is ever given as a simple yes, it
> would be an incorrect answer.

Doesn't prove that they are "NOT related". All you have proved is that they are related but unpredictable. You have already admitted they are related when you said they have the same power source. You simply cannot have it both ways. If they have the same power source, they are related.

> Can anyone define any type of relationship or interaction between
> common mode and differential mode impedances in systems that always
> occurs, and follows a rule or interaction between the two that always
> occurrs?

Your example of a solar system is the best analogy I can thing of. Can anyone define any type of relationship that will exactly predict how many planets a solar system will have or exactly where they will be located at a certain time or exactly what their rotation is? The answer is NO but all of that can be measured. The fact that you are ignorant of the orbit of the second planet in the Alpha Centauri Prime system doesn't mean it cannot be measured.

This concept that if you don't know something, it doesn't exist is extremely troubling, Tom. Just because you don't know the relationship between the second planet and its star, Alpha Centauri Prime, doesn't mean that a relationship doesn't exist. Or do you believe that existence is defined by what is in your mind?

Hi Alan,

Take a standard dipole and form it into an open loop in the horizontal
plane (bend the ends around in a box shape so that the tips come
together, but do not connect).

Hi Cecil,

This is one problem of the ongoing debate, you have first presumed a relationship to then prove that lack of evidence does not deny the relationship. It begs the question, if you have no way of determination, how is that you can make an assertion in the first place? Faith based arguments don't go very far.

> appears to be a relationship in at least one system.

Yes, we have measured the relationships of the planets to the star in at least one solar system. I cannot tell you how the planets are related to the star in any other solar system because it has not been measured. Because other solar systems have not been measured, do you assert that their planets and stars are "NOT related"? Ridiculous in the extreme!!! Antenna systems are like solar systems, Tom, they are all different. That doesn't make their components "NOT related".

> 2.) The reason you can not give me an answer as to how they relate in
> all systems is you are ignorant about how or why they are related.

Yes, just as I am ignorant of most other solar systems. Can you tell me how many planets orbit Alpha Centauri Prime, what is the diameter of their orbits, and what is the duration of their rotations? If not, does that mean that Alpha Centauri Prime's planets are "NOT related" to their star? Again, ridiculous to the extreme!!! Oh, by the way, thanks for the solar system analogy. It is perfect. Planets, orbits, and rotations are certainly related to their stars but are definitely unpredictable based on our present knowledge.

> 3.) You say they are related, but in an "unpredictable manner".

Yes, just as planets and stars are in other solar systems. Just because you cannot predict the relationships doesn't mean they are "NOT related".

> Is that about it?

Let me see if I understand this about the Alpha Centauri Prime solar system.

1. You cannot tell me how the planets are related to the star. Therefore, those planets are "NOT related" to their star?????????? Do you realize what utter nonsense that is?

2. The reason you cannot give me an answer to my questions about the Alpha Centauri Prime solar system is that you are ignorant of it just as I am ignorant of antenna conditions until I measure them?

3. You say the planets and star in the Alpha Centauri Prime solar system are "NOT related" because you are ignorant of their relationship? If you were not ignorant of their relationship, would they magically

become related? Does your omniscient power really extend all the way
to Alpha Centauri?

It may if the source of the Common Mode current is the Differential
Mode potential (not a general statement, but certainly an ordinary
occurrence).

>
>3.) Is common mode voltage or current always phased locked to
>differential mode voltage or current?

NOTHING is always. Aside from the metaphysics of this question, it is
an ordinary occurrence. Aside from the ordinary occurrence, Common
Mode is not strictly a product of the Differential Circuit but is
heavily influenced by it (they both share the same circuit paths and
correlation is inescapable). Strictly speaking, Common Mode artifacts
can exist in the total absence of Differential Mode excitation (the
opposite situation also exists).

>
>4.) Do any of the three above always occur in systems able to support

R1 / R2 = R3 / R4

The simultaneous consideration of both Common Mode and Differential Mode circuits (the are only separate circuits in their consideration for solution by means of mesh or nodal analysis - an artificial construct used to perform superposition) is nothing other than a bridge. A bridge imbalance anywhere is an imbalance everywhere.

Tom, W8JI insists common-mode is unrelated to differential-mode.

My reply is: Changing differential-mode voltage inevitably produces a common-mode voltage change. Thus, they are related.

Tom replies, common-mode impedance can be changed without changing differential-mode impedance.

This may seem plausible. Maybe we can coil up a few turns of coax in our feedline and increase common-mode impedance, and surely the internal differential-mode impedance of our coax is unaffected.

Where the feedline meets the antenna, impedance ia volts over amps. Changing the amps taken by the common-mode changes the impedance at this point, so it affects the differential mode volts and amps too. The formula which is inviolable is Ohm`s law.

Similarly, changing the differential-mode impedance affects the common-mode volts and amps.

Tom doggedly argues, unrelated!

Never mind the network principle that current in one conductor producing a voltage across another is proof of a "mutual impedance".
Mutual means involved together (related).

Tom`s contention is absurd.

Simple analogy of this dispute (Analogies are always imperfect but sometimes get a point across.) is I might say when I change the voltage across a voltage divider, the volts between a tap and either end change too. Therefore the volts at the tap are related to the volts across the whole divider.

Tom, it seems to me, argues: I can move the tap as I please, therefore there is no relationship.

Best regards, Richard Harrison, KB5WZI

Hi Richard,
evidently, Cecil wants to win
this debate at any cost: using the logic
you pointed out, arguing current while Tom
argues impedance, using improper analogies (planetary systems), telling Tom
what Tom is supposed to be saying, etc.
This is a pretty interesting display of ego-
clash, but it doesn't do much to advance
the understanding of those of us who
want to learn about antennas.

Hi Richard,

This is more than complex by a tenth and states only a general
observation tacked onto the argument without consideration for simpler
explanation (much less a more satisfying one).

Delving into phasors and the complexity of impedance is wholly
unnecessary and going on into mutuality is beyond the pale. The
discussion of the relation of Common Mode to Differential Mode is far
simpler and requires no appeal beyond simple ratios (much like Ohm's
law that you subsequently painted up like a tart).

The entirety of this discussion is subject material of EE101, Basic
Networks, employing Kirchoff's laws with mesh or nodal analysis.
Given the proliferation of discussion and the total abandonment of
this simple treatment, I suspect all debaters prefer arguing with
their own monsters of invention. This, like asking for the reference
implied by the usage of the term Common, appears to be a strain for
all to conduct through completion.

Hi Richard,

This in some way resurrects your earlier embellishments (but then you
post two follow-ups that tend to negate this gain).

Ratios are the ONLY meaningful discussion in light of the complete
circuit being laid out before us and such ratios would answer all
questions, even the complex ones with artificial constraints.

This is all far, far simpler than any of the mental gymnastics and
finely honed wording that has gone before this.

Being phase-locked and having a common power source is a faith
based argument??????? Are you willing to go on record as asserting
that common mode conditions are "NOT related" to differential mode
conditions?

The only thing being discussed here is whether the following statement is
true or false:

Common mode conditions are NOT related to differential mode conditions.

The statement is proven false by the observation that when the differential
mode currents go away at key up, the common mode currents also go away.
Therefore, they are related.

>

Hi Richard,

I won't argue for Tom, but Common Mode paths are separable from
Differential Mode paths in analysis. In that sense, yes they are
unrelated. The Differential Mode may be entirely free of Common Mode
issues until someone upsets the apple cart with a real circuit
addition or through a change of symmetry (both products of an outside
agent and as such identifiable and separable at the time of
commission). However, as a circuit (and both Modes are confined to a
single, over-encompassing circuit) all effects are wholly related.

The resolution is that these circuits are in a bridge configuration
and yes, each element of the bridge is independent of the other, and
yet if any element were to change, all the remaining elements would be
affected through the actions of currents and potentials redistributed
through the action of the imbalance brought to it.

As I said earlier, cause and effect are being intermingled
indiscriminately through the absence of discussion of the entire
circuit which reveals the reference of the Common. As none here have
attended this basic consideration, a resolution for them is impossible
to obtain.

The real problem of these discussions is that none here will back away
from their myopic perspective to describe the entirety - each wanting
to describe an elephant, close up, in his own blind way.

Source record: 139504

Let me venture a guess before the experts weigh in. I think a 75 meter dipole has a 13 to 1 ratio if it is tuned to 3850 i.e 3850 *13 = 50.050 so the 75 meter dipole should actually work by itself on 50 mhz but I think it needs to be closer to 4 mhz to reach resonoance at 52 mhz 13 * 4 = 52. So by the time you prune enough wire to reach 52 you're out of the 75 meter band or close to it. I am not sure which portion of the 6 meter band you want to operate on but I think that the 75 meter dipole in parrellel with the 6 meter dipole will interact since their resonant lengths are at least close to each other. So I think that you have a 6 meter dipole that is fairly close to resonance in parrellel with a 13/2 wavelength dipole that is somewhat lower in frequency than what you desire. Multiwire dipoles work because the dirfferent dipoles are far apart as to resonant frequency. As to a solution hmmm..... perhaps I should leave that to the experts. I'm sure you've already discarded the idea of seperate feedlines.

Tom, W8JI wrote:
"So you are saying Ohm`s law is the formula for determining mutual coupling between common mode and differential mode impedances.

If the differential-mode energy doesn`t exist, neither does the common-mode. The only way common mode comes into existance is coupling between the circuits where the modes prevail. This coupling has a name which is used for its quantification, "mutual impedance".

The mutual impedance formula is found in many texts and is simply an extension of Ohm`s law. This is from a WW-2 era Terman`s "Radio Engineers` Handbook" page 278:

Mutual impedance = Z12 = -E2 / I1

That`s Z = E/I , or Ohm`s law, where we have voltage in one wire and current in another ratioed.

Hi Steve,

I was speaking of our group's participation in our own judged challenge, not the un-registered lottery which may (and in all likelihood) contravene a number of laws. I have notice a similar effort being proposed that is simply the pimping of amateurs for commercial prospects - in short, hi-grading others' antenna work to leverage a new product. Worse is that no boon will fall to the individual whose work is stolen.

This is repetition from my Tue,Jul 2, 2002, 9:30am posting.

"The common-mode signal using the center-taps of the transformers does not mix with the wire-to-wire differential-mode signal because there is no "mutual impedance" shared by the signals. Without a mutual impedance, one signal does not become a "function" of the other signal.

Unbalance the system, and the signals mix. One becomes a function of the other. When you change the differential-mode voltage it affects the common-mode voltage.

This is the same cause and effect we have been discussing with transmission-line imbalance or antenna imbalance---."

For newcomers who question the existance of signals between center-taps, it`s an ancient practice. Phone companies have turned two voice circuits into three by using center-taps in one phone line to create one side of the "phantom circuit", and the center-taps in the second phone line to create the other side of the "phantom circuit". A connection to earth is not required for creation of a phantom circuit.

Use of the earth return has been used for signaling, supervision and voice, however. A ringing current signal is effective over a longer distance when it is using both wires of a pair in parallel against ground.

The phantom circuit is extraneous to the point I have to make. For all I know, Tom, W8JI, has balanced lines and antennas in mind. This would be a trivial case where no coupling exists as there is no common-mode.

My argument has been concerning a substantive case concerning imbalance and a common-mode.

Best regards, Richard Harrison, KB5WZI

In a previous posting I gave an example of a balanced transmission line with center-tapped transformer windings at its ends. I wanted to illustrate the difference between balance and imbalance, differential-mode and common-mode.

I said the two center-tapped transformer windings were connected to create a balanced bridge until something is done to produce imbalance.

Common-mode (unbalanced means not balanced to ground as Richard Clark noted) signals could use the center-taps to inject/extract signals without offending the differential-mode signal, and vice versa, so long as balance is maintained.

Richard Clark mentioned the bridge in his posting. He may have the key that makes mutual impedance apparent or at least it may show how imbalance sends a signal through a common mode circuit if it is identified with the bridge circuit. Thanks.

Without imbalance, there is no common mode on our transmission line unless we put it there.

Best regards, Richard Harrison, KB5WZI

Richard Clark wrote:
"Differential Mode may be entirely free of Common Mode issues until
someone upsets the apple cart---."

Exactly, but the argument is not about a system devoid of common-mode.
There has to be common-mode to argue: Is it related to
differential-mode, or is it unrelated to the differential-mode?

Cecil has it right. You can`t key common-mode on and off by turning the
differential-mode on and off if the two are unrelated. That`s a complete
violation of both art and science. It may even be a violation of
humanity.

Best regards, Richard Harrison, KB5WZI

Richard Harrison wrote:
> Without imbalance, there is no common mode on our transmission line
> unless we put it there.

That's essentially the physical experiment that I ran. I have gone
to great lengths to keep my dipole balanced going so far as to measure
the amplitude and phase of common mode currents on my ladder-line. When
I configured my well balanced dipole as an off-center-fed dipole, the
common mode current increased by a magnitude. Doesn't that prove that
common mode conditions are related to differential conditions?

If common mode conditions are "NOT related" to differential mode conditions,
how does one ever become an expert on common mode conditions? Prayer?
ESP? Omniscience?

Gary, you missed the point. If you didn't know anything about our solar system and were trying to predict the existence of planets and their orbits and rotations, you would be up that proverbial creek without a paddle. The entire point was that we had to make measurements before we knew what was going on. There were no first principle formulas that would predict the number of planets along with their orbits and rotations just as there are no first principle formulas that will predict the magnitude and phase of common mode currents. If we want to gain knowledge of them, we have to measure them, just like the planets. Not knowing the number of planets/ orbits/rotations in the Alpha Centauri Prime system does not mean that the planets are "NOT related" to their star.

Hi Chris, Let me be the first to say "are you serious"? Why would anyone send you $7.00 for instructions that are in numerous books, web sites, magazines ect.? My homebrew 1kw tuner cost about $125.00, and yes "why buy" when it is very easy to build. I can work 160-10m with a ladder line fed dipole, the loss in the tuner is small. Your GAMMA MATCH antenna will work one band and the match is at the antenna.
Why would it take you up to 3 weeks to get this well know info out? If anybody wants to send me $3.50 (half price) I can supply info on gamma, beta, tee, hairpin and other well known matching techniques;-). Good luck Chris

Hi Richard,

Yes, the discussion in hand is with Common Mode artifacts, and yet
they can exist in total isolation to the Differential Mode as clearly
described by your hybrid telephone circuit.

The two MAY BE related, but that is not a fundamental property of
Common and Differential Modes but rather in their topology. Both
circuits exist everywhere and yet only become a problem (or become
evident) through issues of balance (topology). It may be an ordinary
circumstance of Amateur applications, but that circumstance is quite
rare as a specie of general note.

What Cecil notes and measures is not a general condition defining the
situation, except for his/our limited experience. This discovery of
his relates to the adage: if all you have is a hammer, all problems
look like nails.

<***JUMPING UP AND DOWN WAVING ARMS***>

Have you guys yet agreed on what you're discussing ? Currents or impedances
?

Obviously the current are "related" by any reasonable definition (phase
locked, key up versus key down, and all that common sense obviousness). One
point to Cecil.

What about the impedances (differential mode versus common mode) ? It would
seem reasonable that the impedances could be (in the general case)
"unrelated". It might be very difficult to vary each independantly of the
other, but it should be possible to set *any* combination of the two values.
One point to Tom.

These are *not* contradictory. Different subjects.

Cecil, I notice that you've slipped in the newly-invented phrase
"common/differential mode conditions". This doesn't help.

--

The best debater that I ever met is a guy named Bob. He would simply listen
without saying a word except to ask a few clarification questions and he
would ensure that he understood your position fully. Then he would say a
single word that would force you to change you mind.

He and I were once debating the benefits of 'virtual reality'. His single
word that carried the day was 'pterodactyl'. Men-of-few-words world
champion. Amazing.

==========

Dear Chris,

Please don't be offended at this interruption. You are going about things the wrong way. You will never become a billionaire with Plan A.

You are undervaluing the value of your no-doubt considerable contributions to radio engineering.

Over here $7.00 will buy a packet of 20 cigarettes. You won't get many takers on THIS side of the pond. It's not worth the risk and trouble of a credit card transaction.

It is suggested you adopt Plan B. Up the price to $70,000. G5RV and prospective CFA manufacturers, marketing departments and salesmen will then begin to take you seriously and consider switching.

It is time the old junk was cleared off the shelves. Just think of the royalties waiting to be collected from the ill-educated suckers, Ph.D's even.

Blaze your way into the 21st Century with the GAMMA MATCH !

By the way, have you considered following up with the Delta Match ?

Regards, Reg, G4FGQ. ;o)

What astronomers note and measure about our solar system is not a general condition defining the situation with all solar systems. Every solar system is unique. Every antenna is unique. That doesn't mean that planets are "NOT related" to their stars or that common mode conditions are not related to differential mode conditions during transmit with an amateur radio antenna.

David,
I have a coax cable, two 120vac circuits, and a Cat5 cable running thru a 3/4 inch PVC pipe. It's a tight fit but I get no crossover, RFI or crosstalk.
I took the precaution of installing Ferrites on Everything on both ends (except the Cat5 because I didn't want to ruin the internal twist.)
I would have used a bigger pipe (hindsite), but it works.

Rick,
I very much doubt if it's the metal pole. I
would think that the 'problem' is the interaction
between the 80 meter and 6 meter dipoles. The
80 meter dipole shouldn't be affected to any great
extent, but the 6 meter dipole certainly will be!
The 6 meter dipole's impedance is lowered well
below 50 ohms.

I would second the idea of using larger pipe. I have a very long run
under ground and used 2"
pipe. It filled up quick. I don't think I could ever pull another line
in it now. Be sure to use the
"long sweep" elbows. Much easier to pull wire through. Or even two 45
degree bends
together. I would bring the pipe up along side the concrete rather
than inside it. Makes for
easier digging if you do have to get at it for some reason.
All lines run up the tower together so there shouldn't be any problem
with them together in the
ground. It may actually help as far as lightning currents go with the
mutual coupling to each
other.

> We are discussing conditions.

What's a "condition" ? When did you make this new phrase up ? Maybe about two minutes after my posting where I reiterated my 9-month old opinion (...what we have here is a failure to communcate...) ?

Is a "condition" a current, like you've been measuring ? Or is a "condition" an impedance, onto which Tom has been holding steadfast ? Or are you trying to muddle the waters by brushing off this 'minor distinction' ? You're being very naughty if you're intentionally trying prolong the argument by introducing the word 'condition' - a word that brushes off my several attempts to point out the 'disconnect' (currents as opposed to impedances) between you and Tom et al.

It is blatently obvious that the currents are related. That's 'dough-head' obvious - almost not worth mentioning. Pull the main household circuit breaker to confirm. Duh... Tom has agreed with this already.

It is also fairly obvious that the impedances (differential 'versus' common mode) might be related, might not be, might be inversely related, might be vaugely proportional or not even close - all depending upon which of the zillions of real world antenna (and ground) parameters you might care to vary, in what combination and over what range. They're both a function of everything. I would call that more-or-less unrelated; you may call it 'Betty' if you wish.

The above two paragraphs are fairly self-evident.

[I'm patiently awaiting the long-overdue death of this hijacked thread so that I might be able to introduce another (hopefully very interesting) "BACK TO BASICS - ..." discussion on the topic of vertical antennas.]

That's right, they are totally different things. My point exactly, and
something we should never forget!

The thing I was trying to point out, and the thing that trips people
up when they are analyzing systems, is ASSUMING they are related and
that a low differential impedance means a low easily cured common mode
impedance.

The EH people and people trying to help them design a good test make
the same mistake Cecil and Harrison made with the tuner, assuming
throwing a few beads at a 50-ohm differential mode impedance can
change the common mode system signifcantly.

Moving beyond the silly useless argument or diversion Cecil and
Harrison interjected, look carefully at the feed system for the EH
antenna. You will see that in that system, the shield of the cable is
driven by the full force of the power used to drive the antenna
element if it is indeed phased as they claim. Adding common mode
impedance to the system is futile, unless the common mode impedance
added is extremely high, becuase they designed almost a perfect system
for backfeeding the shield of the cable.

As a matter of fact, if you eliminate the shield path it becomes
totally impossible to feed the antenna elements with any amount of
phase shift different than a normal dipole.

Have you looked at that system? Anyone who has, and who understands
simple differential and common mode circuits, would understand there
is no way to feed the antenna as claimed UNLESS the shield received
just as much current as the elements!!!

Since radiation is directly tied to ampere-feet of spatial conductor
length, the longer feed line shield...even if it is only twice as long
as a two-foot element...would have significanly more radiation than
the EH antenna itself if the antenna is phased as they claim.

Most interesting os the fact that the phase shift they specify coincides nearly with maximum feedline current on the outside of the shield, and if that current did not exist the phase would also disappear.

Look at the circuit on the EH antenna page, described in the section on phasing the antenna.

Beside Richard's suggestion, there are also turnstile antennas.

That would be two dipoles crossed at the centers in an X.

You feed one dipole with 90 degree lead or lag from the other.

The resulting pattern is nearly perfectly omnidirectional. You give up only three dB to pick up 20 dB or more in the dipole's normal null areas.

It is a wise and common solution when people want to communicate in all directions without using a vertical.

Besides, celestial mechanics is a mature
science, as is electromagnetics. If common mode impedance (and I mean
only impedance) and differential mode
impedance are related, somehow, Cecil,
with his fine engineering education should
be able to define and explain the relationship much more clearly than he has
heretofore.

There is no reason to seperate the control cable from signal cables.

They will be fine together, and it is even better for lightning to
keep them all in a bundle.

I would, however use larger conduit. I would also use cables suitable
for direct burial cables if there is any chance at all water will lay
in the conduit. I would NEVER use air core cables in a horizontal span
and especially if they are run underground, unless you pressurize
them. So don't use that fancy but troublesome Belden air insulated
coaxial cable.

Yep again. There are many ways of tuning antennas. I think you've
proved yours to work well. Since he didn't specify a feed line length
one assumes it to be random whether coax or ladder line.

StarGazer <pti@capnet.com> wrote in message news:<3D1B5D9F.1DB7E03C@capnet.com>...
> I bet you have a lot of loss on your line.

Hi S.G.,
You know, I really don't know if I have a lot of loss on my line. I've never bothered to do any measurements, and I'm suspicious of the whopping losses predicted by TL or TLA.

Why don't I bother looking at the losses? I believe I've tried to minimize whatever losses may be in the system. True, there is a loss in the tuner. But in using ladder line, I've minimized any additional line loss under high-SWR conditions. In using a choke balun, I've minimized any loss that may occur if I try to use another type of balun at a frequency it was not designed for. When I replaced the dipole and feedline with a similar setup in April, I noticed that the ladder line was corroding badly after being up for 4 years. There's another loss to consider.

Why don't I bother looking at the losses? Because I know the system works, and works under tough contesting conditions. I've worked the west coast from Maryland using 5 watts, and I've worked Europe and South America using 50 watts. The big boys with their Yagis usually hear me the first time.

My first antenna was a coax-fed dipole for 40 meters. Later I added a second dipole for 80 meters at the same feed point. A good friend down the street helped me put up a loop skywire. I wanted to fuss about the length and about the feed point. He said don't worry about it and put up the largest loop possible in my yard. He then proceeded to tie knots in the wire at the feed point. It worked great, and even better when I changed the coax for ladder line.

What's the bottom line here? You've got the right approach in asking questions up front. But put up something, try it, and see how it works. Try experimenting with different types. Change it around when it needs improvement.

Try slightly offsetting the feedpoint of the 6m legs. IE: take a
little off only one side or the other to get the best match. Maybe
even take what you took off one side and add it to the other. You will
need to try each side to see which works the best. You "should" be
able to get a near perfect match with a little tweaking. The
offsetting of the feed acts as a gamma match of sorts. MK

The 120VAC circuits may need their own conduit. This isn't for noise
reasons, but to keep things legal per the electric code. Check with
your local building department or a licensed electrician before mixing
different types of circuits in the same conduit.

I'd rather have a butternut if I were to buy a store bought "all band"
vertical. It has lower loss on the lower bands. And almost certainly
lower loss on the high bands as well, although the difference will be
less drastic on the higher bands. You will need radials for a
butternut to live up to it's potential. MK

Hi Cam -

Some questions, if you please:
1. Is the antenna you're talking about here the 130 foot, ladder-line fed dipole
that you mentioned in an earlier thread?
2. I assume the 3:1 SWR bandwidth refers to a constant setting of the tuner.
Is that correct?
3. Are these bandwidths centered around the 3.993 and 7.216 frequencies
mentioned in the earlier thread?
4. Why is the 80m resonance set so high (half the BW out-of-band)?
Is it because the 80m and 40m resonances are interactive, and you
like the 40m resonance where it is?

I have not been able to get comparison figures ANYWHERE so VERY INTERESTED in where you got loss (efficiency) figures especially showing a 1/4wl vertical Butternut being more efficient than a vertical dipole (GAP).

Hi Alan,

the german standard ham antenna 'bible' proposes a 90 degree bent full wave
dipole as an omnidirectional antenna. According to a short NEC run it is
omnidirectional (3 db difference between min and max field) in the
horizontal plane. Disadvantage is that it is slightly stronger straight up
than it is in the horizontal plane. Maybe that Roy's EZNEC demo can model
this.

The matching can possibly done by using a quarter wave section of 450 ohms
twin lead.

==========
Hi Gary, for the sort of equipment and lines used by us amateurs the break-even point is about 21 MHz. Above that freq the variable-length transmission line transformer has the lower loss. But I would never discourage use of such a simple device even on 160m. What's a dB anyway? CAM's method is clearly the economic option.

From where I sit at this keyboard I can see on the inside window ledge of the shack a 4-by-75pF tuning capacitor. There is a plastic tube which was once a high blood pressure pill container. There are also 6 alligator clips and one crocodile clip. I have dispensed with the cigar box. I gave up smoking 5 years ago. An antenna wire comes through a 3/8" hole in the wooden window frame. I have never used a commercial tuner and I'm proud of it. I've only seen pictures in the magazines.

He hands out an IEEE paper that shows measurements of a 1/2 wl tall BC band vertical. When the fed that same antenna as an elevated feed groundplane with eight 1/4 wl radials mounted 1/4 wl above ground, it was only slightly weaker than the ground-mounted counterpart with 120 radials.

The interesting thing is he trys to use that paper to show his GAP vertical is more efficient than other verticals, when the paper shows nothuing of the sort. It simply shows a groundplane antenna with eight radials mounted 1/4 wl above earth is only slightly weaker than a 1/2 wl vertical with 120 radials on the ground.

Big deal.

>Butternut being more efficient than a vertical dipole (GAP).
>
>Alan KB7MBI

Alan,
I agree with him, and so do many other sources.

First I directly compared a Gap to a Butternut in the early 90's as
part of a contract job for an antenna manufacturer. In my
measurements, there was a significant difference between the gap and a
Butternut on 80 meters, almost 15dB as I recall. There was less
difference on 40, but still significant. My 10-foot mobile antenna
actually beat the Gap on 80 meters by a good margin!

Second, QST reviewed a Gap many years ago and found almost identical
results. It had a few good bands where it compared well to other
antennas, but they were all higher bands. They showed a smaller trap
vertical mounted on the ground beating the Gap on lower bands.

Third, there is a book published with independent measurements of
antennas. It is published by Champion Radio Products (they do not
manufacture antennas, they only install them) and shows FS comparisons
which prove the Gap is very inefficient on lower bands. It ranks at
or near the bottom of group tested, except on higher bands. It is
actually significantly worse than the much smaller MFJ no-radial
vertical on some low bands.

It would be worth getting the Champion Radio book on vertical comparisons before making a decision.

That's silly.

In his one particular example the sources come from one source, but
they don't have to do that! As a matter of fact, in real life, there
are probably multiple sources driving the system if you want to pick
nits.

What I am saying is one has nothing to do with the other as an overall
statement or concept of how the system works. While they CAN be meshed
at some point in the system, they do not have to be. And no matter
what the situation, we HAVE TO consider them separately and
independently. If we lump common mode characteristics with
differential mode, we will reach wrong conclusions about system
behavior unless through sheer dumb luck they happen to behave
similarly.

Cecil and Harrison gave some of the best examples of problems it
causes when you lump them together. Cecil did that, and argued that
moving a choke balun from the output to input of a floating tuner
improved the system balance or balun effectiveness, Harrison agreed.

I'm amazed they cling to this idea, after it got them in trouble in a
VERY simple easy-to-understand system.

Rick,
You've answered your own question. The 80 meter
antenna will lower the input impedance of the 6 meter
antenna (14th harmonic). The 6 meter antenna shouldn't
affect the 80 meter much, if any.

I see your point. It is a very common mental trap to get hung-up on only the transmit mode (I'm feeling guilty). What we need here is a single clear 'counter-example'. Allow me to see if I can create one that might be agreeable to you and everyone.

Example: Imperfect dipole in receive mode with some common mode currents. The normal differential mode (dipole) would perhaps slightly prefer horizontally polarized signals, while the common mode (coaxial cable shield) might prefer vertically polarized signals. Obviously they probably even resonate at different frequencies.

Given this situation (receive mode), the currents could be entirely unrelated (one being primarily a ham signal, the other being primarily the local 'Conntry & Western' AM broadcast station).

Your point seems to be perfectly valid. Thanks.

273. EH antenna Feed System

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-04 11:58:28 UTC
From: 2w8ji@contesting.com
Message-ID: <3d243471.126259905@news.akorn.net>
Source record: 139565

After all the distractions, I'd like to get some other opinions about the EH feed system.

I see some very serious flaws with the theory and the feed system.

First, they assume a "T" network shifts phase 90-degrees but have no way to measure it. They simply tune for maximum FS, and hope SWR is low.

Second, they assume that phase shift is between TWO terminals and NO third terminal is involved. They use a high-pass L driving an inductor in series with an element as the +45 shift side, and a lowpass L driving an inductor as the -45 side.

Since the networks float and drive a two-terminal load, the phase shift at the load has to be 180 degrees, if we consider direction of flow into and out of those two terminals. So the current in the elements, viewed from a distance looking back at the elements, is in phase in each half...just like a dipole.

Obviously the inventors call themselves liars, because if the system DID only radiate from the antenna, it is impossible to have the 90 degree shift they say the syetem requires. It is only possible to have the 90-degree shift while the coax is radiating more signal than the antenna, assuming the coax feeding the antenna is at least as long as the antenna is long!!!!!

With a two foot antenna, a four foot feedline would radiate more than the antenna no matter how you treated the feedline IF the phase shift was 90 degrees as they claim it needs. If the feedline did not radiate that amount, you could not get the phasse shift they say the system needs.

With something so simple and easy to see, why are people arguing the EM theory?? The inventors are calling themselves liars just by the basic circuit theory they use.

My original question was tongue-in-cheek, based on the assumption that people buy trapped multi-band verticals of less-than-stellar efficiency because they are (a) multiband, and (b) omnidirectional.

Your answer, and others', does at least answer the "omnidirectional" aspect. Yet it seems to me that even a single such bent dipole will be far more difficult to erect in a small space than a vertical. And the thought of putting up a multi-band version with its necessary supports is almost overwhelming.

In my present situation, with a 10m x 10m yard, a multiband vertical seems far more practical.

The transmitter energy starts out 100% differential. Some of the differential
energy is converted into common mode energy. How you can deny that is
beyond belief.

Tom and Mike
Thanks for the feedback. I want to say I am not defending the GAP but rather not finding good comparable data. Basically, only guessing at what the lobe patterns are for the various antennas well it just makes it difficult to make good comparisons.

Mike made a good point that for the money you can homebrew as good or better antenna than any of the commercial ones. I know my 33 by 33 inverted-L does a good job. Not as good as some but better than others.

This gets back to my earlier note about all antennas are a COMPROMISE of some sort but knowing what that compromise is is difficult especially with some of the commercial ones.

Tom, I have heard of the report you mentioned but had fallen into the category of taking some comments at face value that the report was flawed and the results not of any real value. I need to get a copy to see for myself.

Thanks for taking the time to share some good information

> tuner. Is that correct?

No tuner. I don't use a tuner. It refers to a constant setting of ladder-line length at 88 ft.

> 3. Are these bandwidths centered around the 3.993 and 7.216 frequencies
> mentioned in the earlier thread?

Nope, that's just the frequencies where 88 ft of ladder-line causes 75m and 40m ham band resonances to overlap.

> 4. Why is the 80m resonance set so high (half the BW out-of-band)?
> Is it because the 80m and 40m resonances are interactive, and you
> like the 40m resonance where it is?

By varying the length of the ladder-line, I can set the resonance to any HF ham frequency. 88 ft of ladder-line is interesting because that length causes resonance on both 80m and 40m within the ham bands. For someone who didn't want to vary the length of the ladder-line, 88 ft would be a logical choice for feedline length on 80m and 40m.

The minimum length of my ladder-line is 86 ft and occurs when I set my ladder-line length selector to zero ft. At that length, resonance on 80m is a little above 4 MHz and resonance on 40m is a little above 7.3 MHz so when I add length to my ladder-line, I can cover the entire 80m and 40m bands. With 86 ft plus 23 ft, I can cover down to 3.6 MHz on 80m. With 86 ft plus 3 ft, I can cover down to 7.0 MHz on 40m.

> they don't have to do that!

Are you saying that typical ham radio installations have more than one transmitter active on the same frequency at the same time? Get real, Tom, and stop blowing smoke. Your argument is getting more bizarre all the time. We are discussing single transmitter systems where virtually all the energy originates as differential mode energy.

Please answer the following questions, true or false, Tom, and we can settle this entire argument.

1. Common mode currents and differential mode currents are "NOT related". _______

2. Common mode currents and differential mode currents are related. ________

One is true and the other is false, Tom. Which is which? If you refuse to answer, we will know that you are just throwing up a smoke screen hoping the argument will go away and people will forget that you were ever so blatantly wrong as to assert that two energies that share a common power source are "NOT related" and that typical ham radio systems have more than one transmitter operating on the same frequency at the same time.

If common mode currents are "NOT related" to differential mode currents, why can I hook up a code practice oscillator to my common mode current meter and copy the Morse code?

> Cecil and Harrison gave some of the best examples of problems it
> causes when you lump them together. Cecil did that, and argued that
> moving a choke balun from the output to input of a floating tuner
> improved the system balance or balun effectiveness, Harrison agreed.

The present argument has absolutely nothing to do with a tuner or balun, Tom. And moving the balun from the output of my tuner to the input

of my tuner actually *did* reduce the measured common mode current by 27%.
Your model assumes "zero resistance" when there is no such thing. Your
model assumes "zero wavelength" when there is no such thing. Your model
assumes "no tuner leaks to ground" when there is no such thing. Your
model simply does not match reality, Tom.

You are going to buy into Tom's smoke screen? The context has obviously
always been a single transmitter transmitting into a single antenna system
and considering all other signal sources to be negligible. Tom is just trying
to mealy mouth his way out of the corner into which he has painted himself.

Tom, W8JI wrote:
"In his one example the (signal) sources come from one source, but they don`t have to do that!"

True, and useful I thought to illustrate how balance can prevent coupling between modes. But this argument has been about one transmitter, and only one transmitter, supplying energy on more than one path.

Tom also wrote:
"What I am sayimg is one (mode) has nothing to do with the other as an overall statement or concept of how the system works."

When the system is unbalanced, common-mode results. Imbalance produces it. Common-mode isn`t cut-loose and sent into the world on its own. It is part of a continuous-flow process. Cease the differential-mode energy, and the common-mode energy ceases too.

Tom also wrote:
"While they CAN be meshed at some point in the system, they don`t have to be."

This discussion has not concerned unmeshed, state-converted, stored and forwarded, or any such decoupling. "Unmeshed" is simply a diversionary tactic.

Tom also wrote: "---we Have To consider them separately and independently."

Once a system is set, we can determine the magnitude and phase at any point in the system. If we don`t change the system or the frequency, the magnitude of one mode is the same percentage of the other.

Tom also wrote:
"---and argued that moving a choke balun from the output to the input of a floating tuner improved the system balance, or system effectiveness."

Context is everything here.
Core saturation is a function of volts across a coil.
Current takes a fork in its path according to relative ease in its paths.
Impedance of a conductor depends on distance in wavelengths from a discontinuity.

Tom claimed victory for his claim that it makes no difference where the choke goes. That is settled in the context chosen then.

Tom still claims that killing two birds with one stone doesn`t prove their deaths were related.

Best regards, Richard Harrison, KB5WZI

Hi Richard,
I've used what I've found on my shack:
at first two big toroids (back the TX) with no change in EH performance,
then a YOKE core (as a friend calls it) directly on the feed point
with a lot of coax turns...
that's all!

Hi Jeff,

Your example and analysis are good as far as they go. However, there
is nothing to preclude the same Common Mode current flowing during
transmit. The difference would be in the transmitter exciting the
Common Mode far above and beyond those original Common Mode currents
derived from other sources.

Your description of the receive state is equally applicable to the
transmit state (and versa vice) because it is the topology (the
imbalance) which gives rise to the effects noted, not the impedances
(except, insofar as to insure magnitudes that are measurable). This
is found in the answer to the query for a simple equation showing
relationships:
R1 / R2 = R3 / R4
which, sad to note, goes without recognition. The original query
appears to have been a rhetorical device only.

However, Common Mode can remain a considerable problem even if the
topology is apparently benign. Through the combination of impedances
and a path to ground (balanced albeit), electronic equipment
potentials can be raised to the point of interference or catastrophic
failure. This is a specification that goes by CMRR (Common Mode
Rejection Ratio) for the interference, compliance for outputs, and
input potentials exceeding supply rails (a very common failure mode
that takes most by surprise when they short-cut their ground
coverage).

What this says is that even in balanced configurations, considerable
Common Mode current can be injected into the system (possibly
invisible to Cecil's method of detection, it being applicable to a

small subset of the range of possibilities). This fact is lost on most who, as I have complained, are all too ignorant of the complete circuit description and where the reference, Common, is located.

Richard Harrison provided a compelling example found in the Hybrid telephone circuit where the control and supervisory path is shared by the subscriber, and yet the subscriber is wholly immune from that traffic. The supervisor activity takes place entirely in the Common Mode domain and the traffic passes through the Differential Mode connections without the subscriber's notice. Here the Common Mode current is nearly on par with subscriber's Differential Mode current (a ratio that far exceeds even the characteristics described in these threads). A threat to the subscriber comes when that same supervisory circuit is struck by lightning (or fallen power line, or...) and raises the Common Mode potential seen at the subscriber's telephone set. Sure, by the nature of balanced Common Mode, the anal argument would offer you infinite protection, reality has born out evidence to the contrary on one or more occasions.

The restriction of discussion to limited experience yields a dangerous mind-set (the presumed isolation from Common events). People are killed due to their ignorance of where the Common of Common Mode resides.

Hi Tom,

Why? I wouldn't count on them understanding their own theories, much less established science. The EH design (as well as a multitude of others) contains no more than a handful of components, and yet they offer only a special few ("belief circles" again) can cope with the complexity to achieve (unverified) success.

This techno-anderthal crew, when faced with the comparative engineering miracles of their own transmitters undoubtedly believe only aliens who visited us when Atlantis was great could have the technology to build them. (Is the EH technology derived from the infamous alien anal probe? This and other mysteries will be explored following our commercial break for Stefano's Area 51 special matching device.)

Richard, the context was (and is) a single ham transmitter feeding an antenna system mounted above earth ground. Why is it dangerous to discuss something when the context is fully known? Seems to me the only danger is that Tom might be proven not to be omniscient.

I didn't see anything that was questionable in the vertical measurements, other than we have to make some allowances for instument errors. They tend to ignore the fact instruments and methods are less than perfect.

When someone directly compares multiple verticals on groundwave and one is 10 or 15dB weaker than a few others, you can bet the thing is a dog. This is especially true when sky wave data taken over time in two other reviews or tests almost perfectly agrees with the groundwave data.

If someone told you the Vertical Comparison report is flawed, I'd sure like to read why.

Now I do question the tribander data they took, because they measured tribanders over a 1 mile groundwave path. It is never a good idea to measure horizonatl antennas over a long groundwave path, especially when the antennas are directional and the path is cluttered with things that can scatter the signal.

Omni-verticals are an entirely different matter.

There is no technical reason the Gap should be a good antenna on lower bands, and many reasons why it should not. When you add that in to the measurements, they make sense. Nothing raises a red flag.

303. High Dipole vs. Low Beam

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-04 18:50:40 UTC
From: Greg Knapp <gknapp@freshrain.org>
Message-ID: <4O0V8.22081$A%3.262783@ord-read.news.verio.net>
Source record: 139444

Which is better for pure gain (signal delivered at the receiving site-which could be domestic or DX-in other words, for general use): an A3 up about 30 feet or multi-band dipoles (to be used on 10, 15, and 20) up at about 60 feet (at the center)?

I figure the added height on the dipoles over the beam is good for at least an S-unit or more, which would more than compensate for gain of the beam, due to the angle of takeoff--am I wrong on this? The dipoles (which are now at only 30 feet at the center and much lower at the ends, currently work 160 through 10 including WARC bands) would be lifted to 60 feet on a large push-up mast. If I put the beam up, I'd leave the dipoles where they are.

Raising the dipoles to 60 feet would a lot less hassle (unbelievable neighbors and CC&RS--yet they allow TV antennas--so may put a TV antenna on top and disguise the dipoles as guy wires) and money than getting the beam up to 30. I am not concerned with FB or directivity, just the delivered signal on 10, 15, and 20. I do not currently have the option of putting the beam any higher.

Which would you put up and why?

Thanks for your thoughts,

73,
Greg, N6GK

There are dozens of examples. One of the best is the fact that
commercial landline services can simultaneously send different signal
in the same frequency range through the same system, one via common
mode and one via differential, and not have interference.

>Example: Imperfect dipole in receive mode with some common mode currents.
>The normal differential mode (dipole) would perhaps slightly prefer
>horizontally polarized signals, while the common mode (coaxial cable shield)
>might prefer vertically polarized signals. Obviously they probably even
>resonate at different frequencies.

Of course they can. The two modes are unrelated to each other.

>Given this situation (receive mode), the currents could be entirely
>unrelated (one being primarily a ham signal, the other being primarily the
>local 'Conntry & Western' AM broadcast station).

Sure. There is nothing that says the behaviour of one mode influences
the other in any way.

The impedances can change at a different rate along the line, and they
almost always do. The currents can change phase relationship along the
line, even if from the same source and usually do. It's like comparing
two different systems that might or might not be driven with the same
generator, and because in one case we find a cicumstance where
something is related we then go off into na na land saying the two
independent modes are "related".

They aren't related, that is why they can be different and usually
are.

Nice attempt at a diversion, Tom. The context was (and is) a single ham transmitter feeding a typical ham antenna system over earth ground. Your response is typical of someone who just cannot stand to admit that he is wrong. "Oh, that's not what I was talking about. I was talking about something entirely different".

> Of course they can. The two modes are unrelated to each other.

There you go again. In a typical single ham transmitter driving a typical ham antenna over typical earth ground, the common mode signals and the differential mode signals share a common power source and are phased locked to such an extent that the common mode current detector can be tied to an audio oscillator and the Morse code can be copied perfectly.

> Sure. There is nothing that says the behaviour of one mode influences
> the other in any way.

So you are saying that everything in Roy's (W7EL) article about "Baluns: What They Do And How They Do It" is wrong. Have you talked to Roy about your assertion?

> The impedances can change at a different rate along the line, and they
> almost always do.

That doesn't keep them from being related. All you have to do is measure them and report the results. The relationship is stable unless something changes.

> The currents can change phase relationship along the
> line, even if from the same source and usually do.

Not unless conditions change (like rain). Please describe a single ham transmitter system operating into a typical ham antenna above earth ground where the common mode currents are constantly changing at random in magnitude and phase when compared to the differential currents.

> They aren't related, that is why they can be different and usually
> are.

Your argument is getting so far out it is beginning to become "not of this universe". Are you really willing to take a flight into supernatural fantasy just to avoid being found out to be wrong? Why not just declare yourself to be God and be done with it?

Hi Cecil,

This presumes the knowing of the full context, clearly a false presumption. What you mean by "context" is actually the restriction of discussion through artificial constraints that match the limited experience of amateur radio operators. Such restrictions do not remove danger from illusions drawn from such limited examples.

As I mentioned before:
>People are killed due to their ignorance of where the
>Common of Common Mode resides.
and Richard Harrison is the only one to attempt to describe the Common of Common Mode - obviously there are many who cannot.

Hi Cecil,

The context changes by the day? I recall some discussion of an off center fed example for the same discussion. Is there more than one context? How about the "full" context mentioned earlier today? Are there contexts of varying degree?

Rather, what you present are constraints which yield contradictions to generalities offered as absolute statements (does the position of the choke matter? It did/didn't a couple of days ago). The reason these contradictions arose was through the neglect of a general treatment that included just what the reference was that constitutes the Common of Common Mode - a strangely elusive parameter in this discussion.

..
>Basically, only guessing at what the lobe
>patterns are for the various antennas well it just makes it difficult to make
>good comparisons.

Thats easily modeled though. With a shorter than 1/4 wave radiator, the pattern between all the different verticals of the same appx height will be nearly identical. So thats not really an issue on those bands. What has a much greater effect on the lobe angle is the quality of the ground system. That can have a large effect.
As a test, download the eznec demo, and then open vert1.ez "40m" and use no radials. First, run the ff plot and note the angle. Then view the antenna and note the current distribution. Max current will be at the base, and the plot will show a maximum gain angle of 26 degrees with a gain of -.03 dbi. Note the SRC data that shows a feed impedance of about 36 ohms. Next, go into the source menu and place the source at 50% . "halfway up the antenna" Rerun the FF plot. Note that the gain is nearly the same. "-.06 dbi", and at the same exact angle. "26 degrees" Then view the antenna and note the current distribution. The source is now halfway up the vertical, but max current is still at the base. Why? Because the antenna is still a 1/4 wave in physical height, not a 1/2 wave. Note the SRC data. It will now show a higher impedance. This is about the only thing that has really changed much. The only way you are going to lower the takeoff angle is by adding radials under the antenna. The more radials, the lower the angle up until you start to saturate. And to do that, you would need a solid plate as a radial system. But 120 radials get you close enough for gov work. The point is, the place of feed makes little difference in current distribution, or takeoff angle on these antennas. So really all you have to do to compare, is note efficiency. As a further test, make an elevated 1/2 wave vertical. Try it base fed, and try it fed in the center. The maximum current is still in the middle of the antenna either way. And the takeoff angle is still the same. You may notice a slight difference in gain, but this would be so small to be unnoticable in the real world. From the results on the 1/4 wave, you can see why I think neglecting radials on a 1/4 wave tall, "or shorter" antenna with an elevated feed is a huge mistake. Also , you can see the only way the butternut can be superior with all other things equal is though more efficient loading. Butternuts lower loss coil is the main reason it's the best on the lower bands. Hope this makes some kind of sense...MK

>
My primary interest in this question had to do with "constant setting"
(or lack thereof), not the type of adjusting device used. So for my
purposes, this one is a "yes."

BTW, some folks might call an adjustment device used to change the
apparent system resonance at the input of a transmission line a "tuner"--
regardless of whether said device is implemented with lumped-constant
elements or distributed elements. But hey, it's your machine, so you get
to name it.

I see you refer to it below as a "ladder line length selector."
Is that your preferred name?

> > 3. Are these bandwidths centered around the 3.993 and 7.216 frequencies

OK. But this sounds like a "yep," not a "nope," for the specific adjustment
setting in question (88 ft).

> > 4. Why is the 80m resonance set so high (half the BW out-of-band)?

>
It sounds like the setting is fully interactive, in the sense that both the
80m and the 40m "resonances" move (fast) when the line length is adjusted.

Do both "resonances" move in the same direction as tuning length is adjusted
(e.g., more length moves frequency down)?

I agree that the 88 ft length has interesting properties.

> The minimum length of my ladder-line is 86 ft and occurs when I set my
> ladder-line length selector to zero ft. At that length, resonance on
> 80m is a little above 4 MHz and resonance on 40m is a little above 7.3
> MHz so when I add length to my ladder-line, I can cover the entire 80m
> and 40m bands. With 86 ft plus 23 ft, I can cover down to 3.6 MHz on
> 80m. With 86 ft plus 3 ft, I can cover down to 7.0 MHz on 40m.

This sounds like a pretty slick setup.

How many different length/tuning settings do you have available?
How fine are these adjustments, in length/frequency?
How are the selections implemented mechanically (e.g., knife switches)?
How do you stow the tuning line (e.g., spiral coils in insulating box)?
How much space/volume does your LLLS occupy?

Richard Clark wrote:
"---(the imbalance) which gives rise to the effects noted, ---This is found in the answer to the query for a simple equation showing relationships:
R1 / R2 = R3 / R4"

This is the condition at balance of four resistors in a bridge configuration. One of the resistors may be the unknown and another made variable to balance the bridge.

A favorite author of mine was Rufus P. Turner. He wrote many magazine articles and his stuff worked. He also wrote many popular books, and among them is "Bridges and other Null Devices". On page 12 is diagrammed the "evolution of bridge" (not the game) which numbers the resistors 1 through 4 and gives:
"Thus at null the unknown r2 = (r4 / r3) r1."
This is Richard Clark`s formula rearranged.

Best regards, Richard Harrison, KB5WZI

Source record: 139459

"Second, they assume that phase shift is between TWO terminals and NO
third terminal is involved. They use a high-pass L driving an inductor
in series with an element as the +45 shift side, and a lowpass L
driving an inductor as the -45 side.

Since the networks float and drive a two-terminal load, the phase
shift at the load has to be 180 degrees, if we consider direction of
flow into and out of those two terminals. So the current in the
elements, viewed from a distance looking back at the elements, is in
phase in each half...just like a dipole."

Hi Tom. If you look at fig. 4 in" phasing an EH antenna", it is a matching
network for a dipole using both the high pass and low pass L networks. The EH
cylinders are modeled as a series rlc circuit connected to the junctions of L1,
C1 and L2, C2. The shield of the coax is connected to the junction of C1 and
L2, GND? With this model the voltage on the two dipole sections, with respect
to GND are 90 degrees out. But the current in both halves of the dipole would
be in phase.
If you break up the series rlc model of the cylinders into 2 symmetrical
circuits and center tap to GND. (add a third terminal), then the voltages on
the two cylinders are 180 degrees out, as are the currents, just like a regular
dipole. I thought the whole idea was to make the current in the cylinders 90
out. I still don't see how the network presented will produce this.
I promised a friend I would spend a few hours trying out the 40m version
described on the EH Antenna page. Maybe this weekend.

Hi Richard,

That may well be, but the description does not attend the nature of
Common Mode, merely an instance of it. If you were to short the
transmitter of the subscriber's (Differential Mode) circuit, the
Hybrid telephone circuit would still sustain the supervisory (Common
Mode) circuit. Without attention to the detail of the Common of
Common Mode, the statement you quote above is simply the propagation
of a minor example into the myth.

One counter example shows how shallow such errant generalities become.

The center fed and off center fed responded in the same way, i.e. common mode current was measurable with the differential current was flowing and not measurable (using my method) when the differential current was not flowing. The same holds true for my rotatable dipole. Perhaps it is time for someone to present a ham antenna system being driven by an active ham transmitter for which the common mode current flows when the differential current is not flowing or vice versa. We are all awaiting with abated breath for one of you to describe such a system.

Yes, some might, but it wouldn't satisfy the definition of an antenna
tuner (transmatch) in the ARRL Handbook.

> I see you refer to it below as a "ladder line length selector."
> Is that your preferred name?

LLLS for short.

> It sounds like the setting is fully interactive, in the sense that both the

The resonant frequency changes every time the length is adjusted.

> Do both "resonances" move in the same direction as tuning length is adjusted
> (e.g., more length moves frequency down)?

Yes, assuming we are talking about the current maximum points (which I am).

> How many different length/tuning settings do you have available?

I have five sets of knife switches so the answer is 32 (0-31 binary).

> How fine are these adjustments, in length/frequency?

It is adjustable in one foot lengths. That's a little course for 10m but
works OK. On 80m, I use six foot increments.

> How are the selections implemented mechanically (e.g., knife switches)?

I have two DPDT knife switches ganged per loop. The lengths of the loops
are 1, 2, 4, 8, 16 ft. I think there's a picture of it on my web page.

> How do you stow the tuning line (e.g., spiral coils in insulating box)?

The knife switches are located on a plexiglas plate mounted in the window.
The knife switch banks are about 8 inches apart. The loops are on the
outside of the window, vertical, 8 inches apart. No part of any loop
comes closer than 8 inches to any part of any other loop.

> How much space/volume does your LLLS occupy?

A window full on the inside. The loops extend out about three feet on
the outside and are tied up to the eave of my house.

Dipole antenna installed under a major power line (xmitter firmly grounded)
?

(Common mode will be 60Hz.)

I've got one for 20m-10m. Make it out of aluminum tubing available from
Texas Towers and feed it with ladder-line. It works so well I don't
even need a tuner.

Hello Greg

Never had an HF beam. However my 5-band W9INN HF dipole (10-15-20-40-80m) is up at 54ft and my qth is at 5412 ft above sea level. With that combo I have done remarkably well with 311 DXCC countries since 1995. Now I am determined to make "Honor Roll on a Dipole" and do not want a beam. N6KZ (my DX mentor) has repeatedly offered me a free beam and installation but I feel making honor roll with a dipole is very do-able now at this point and will be more rewarding and satisfying to me then with 1500w / 200 ft tower / and stacked mono-banders / on a hilltop. A dipole up high can "work the world"!!

But to address your question I would suggest you run some antenna modeling software and plug in those two antennas and compare.

Richard Clark wrote:
> One counter example shows how shallow such errant generalities become.

Well, there you have it, Richard. All you have to do is describe an antenna system with an active single transmitter in which the common mode currents are "NOT related" to the differential mode currents. According to Tom, that is all of the antenna systems in the world so it shouldn't be hard to describe just one. Your obvious diversionary smoke screens are not helping so how about an example instead? I'm holding my breath.

However, given the statement, "The differential mode currents and the common mode currents are NOT related", the capitalization of the word "NOT" would seem to indicate that they are *never* related. In all three of my antenna systems, common mode currents are related to differential mode currents while transmitting. Thus, the statement is proven false by only one example which violates the statement. The argument has already been settled. All that is left is clowning around and posturing to avoid admitting a mistake.

Hi Cecil,

Why would I confine the argument when there are already common,
general examples available? Certainly the one offered by Richard
Harrison provides a competent one.

I see that there are now two contexts (or more) and yet nary any
revelation of where the Common of the Common Mode resides - an unusual
omission in light of the discussion.

You pine for subscription to the theory of your observation, you
maintain that all has been revealed and yet when I ask for a simple
circuit description none is forthcoming. I have even provided the
basis for that simple circuit (all that is required is the
identification (not evaluation) of the four impedances and Common).
If this is Common Mode current as you insist, a simple test (nearly
identical if not literally so to the one you've performed) at the
Common would easily sustain your argument in its generality and remove
it from the specter of it being of the classification of yet another
UFO sighting.

This is not to say that your measurements, or your thesis, are in
error; but testimonials do not force a proof. You have admitted to
being in error on one iteration of a former "context"; you could well
be right now; however, you have added nothing to the "context" to
raise it out of the prospects of being yet another ordinary mistake.
In fact you have a tendancy to elaborate (as found in the quote above)
where simplification will do. Given you have no response to where the
Common of the Common Mode resides, I must stand aside to withhold

committing to your thesis until the revelation of this simple and
(dare I say it?) common consideration.

Message-ID: <3D24E70E.F31D87F1@att.net>
Source record: 139376

The sun shines on you and it shines on me - common power source. I do certain things as a consequence. You do certain things. These certain things may or may not be the same, totally different, partially alike in some manner, etc. etc. Are they related?

If the sun went out - the power source vanished - would we both be affected? Of course. But absent that event, it seems to me that my sphere of activities while possibly similar in some respects to yours - we both eat, sleep, etc. - are hardly related in a scientific sense. Certainly, there does not exist a set of closed-form equations which rigorously defines the relationship between your activities and mine, all being driven by a common stimulus: the Sun.

In the simple transmitting case, coax feed to a wire dipole antenna, it seems clear to me that the presence of common-mode current on the outer braid of a coax line must arise either from the division of current at the coax braid connection to the antenna in the absence of a balun or from its presence in the induction field of the radiator, or from both.

In either event, the comparative impedances of the system elements involved play a central role in establishing the magnitude of the effects. Whether or not these impedances are known or can be known quantitatively is another matter. But clearly they exist, even if some may be zero and others semi-infinite.

The stronger the differential-mode power component, the more excitation is available for the ultimate production of common-mode current. Thus, any changes in the system which alter differential-mode operation and performance is likely to have some effect on the common-mode current as well.

Since the antenna load impedance, operating frequency, the transmission line Zo, and its electrical length and loss are the prime factors in differential-mode operation, it would seem that any changes in these would affect the power transfer from the source to the load (antenna).

As operating frequency is changed from that of resonance, the input Z of the antenna will change and thus the reflection coefficient of the system will change. Unless compensated by appropriate impedance transformations to account for the load Z change, less of the source available power will be transferred to the load and thereby less excitation becomes available to generate common-mode current.

While there is doublessly an analytical solution to determine the resulting change in common-mode current, it seems to me that a knowledge of the entire antenna system and its environment is quite unlikely to exist in

sufficient detail to support such an analysis.

Thus, my conclusions are

1. Differential-mode operation and common-mode operation are related in some manner highly dependent upon system configuration.

2. They are both manifestations of the overall operation of the entire antenna system, not just the transmission line.

3. An analytical solution to determine the relationship is probably neither feasible nor, in practical terms, even possible.

4. Experimental observations, unless firmly grounded on a complete understanding and definition of the entire system, are highly unlikely to provide much more than additional confusing anecdotal "evidence" that some form and degree of relationship exists.

5. It is entirely possible that Change A in differential-mode operation may have an Effect B upon the common-mode operation within the system. It is also entirely possible that Change A may produce zero observable effect. The existence of either outcome neither proves nor disproves anyone's contention that the two are or are not "related."

Richard's system was not a typical ham system, which is what is being discussed. Please present an amateur transmitter and antenna system where all sources of common mode are negligible except for the amateur radio transmitter, and the common mode is "NOT related" to the differential mode. You know and I know that Tom was not talking about external sources of common mode when he made his statement.

If there is even one antenna system that doesn't agree with Tom's statement, then his statement is wrong. I have three such antenna systems. "Common mode currents are NOT related to differential mode currents" applies to ALL antenna systems. It is not true for at least one antenna system. Therefore, it is false.

"CAM"
> Cute, but we are talking about common mode [current]
> introduced by the transmitter not by external sources.

Thanks for the "cute" - I'm glad that you noticed... :-)

I see your point - like I said before, it is obvious.

But, what about viewing this situation over a longer period of time. It would seem that the magnitude of the common mode current might well vary due to external factors such as ground moisture, rain, water table level, seasonal fluctuations, and so forth. One might imagine a case where everything of a 'technical nature' (xmitter power, antenna geometry, etc) was being held constant and the only parameters that were changing were related to the weather. Imagine that the magnitude of the common mode current varied due to these external uncontrollable factors. Seems plausible. One might be forgiven for claiming that the **relative magnitude of the phase-locked** currents were "unrelated".

Or... Hang your antenna over the Bay of Fundy with its 50 foot tides. To make it perfectly clear, arrange things so that the common mode current just happens to drop to exactly zero when the tide is out (this is intended to eliminate your 'Morse Code' argument for at least a few hours a day). If Tom dropped by during low tide, and dropped by again during high tide, then your two measurements would tend to support his contention that the currents are "unrelated" (except in the almost not worth mentioning sense, half the time).

The input Z of ANY resonant 1/2wl dipole is around 70 ohms....BUT it
can vary down to 40 or up to 80 depending on height above ground..
(but 70 is the accepted "norm").....since the freqs involved
are HF and not VHF, loss in the coax will be VERY small.....and
additional loss due to any SWR mismatch will be even smaller...

SO dont fret.....put it up and warm up the ether! :)

Modeling a dipole in free space that is resonate at 3.7 MHz would have
the feed point impedance at 7.2 Mhz of R 3184 +J2961.

Which means at 7.2 MHz a 100 feet of RG-213 (RG-8 type cable) would
have the additional loss of about 8.4 dB due to SWR.

I would call that substantial.

Danny, K6MHE

Will the above conditions cause the common mode to exist without the differential
power source? If not, Tom's statement continues to be wrong.

So, to sum up...

Assuming that there is only one source, then we must inevitably conclude that there is - in fact - only one source. I'd have to agree with that logic....it almost goes without saying.

:-)

349. A whole new 'back to basics' topic - Monopole fundamentals

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-05 04:20:43 UTC
From: " J. Harvey" <JM002.Harvey_TRIMTHIS_@Sympatico.ca>
Message-ID: <i89V8.9725$MP.1932703@news20.bellglobal.com>
Source record: 139390

I found an interesting report available online (.pdf format) entitled "Dipole and Monopole Antenna Gain and Effective Area for Communication Formulas". It is authored by JC Logan and JW Rockway (a couple of famous 'EM guys').

The thing that I found most surprising was that fact that this paper was written as recently as September 1997 (the topic seems so early 1950s-ish).

Link to report:
www.spawar.navy.mil/sti/publications/pubs/tr/1756/tr1756.pdf

[If you need the free .pdf file reader, go to
http://www.adobe.com/products/acrobat/readstep.html]

Here are the main conclusions of the report in point format:

1) The gain of a monopole (over a perfect infinite ground plane) is twice that of a dipole in free space. 2.16~2.17 versus 5.16~5.17 dB. [Nitpick - shouldn't that be 5.17~5.18 dB since 'times two' is actually +3.01dB not +3.00dB ?]

2) The effective area of a receive monopole is one-fourth that of a dipole.

3) If the monopole and dipole are in identical fields, then the dipole will deliver to a matched load four times the power.

My only important question - is this really 'new' (1997) news ?

It's a very useful debating technique; you can use it anywhere. For example: Assuming that there is....a penguin colony living on the far side of the Moon, then we must inevitably conclude that there is - in fact - ...a penguin colony living on the far side of the Moon.

Richard Clark wrote:
"If you were to short the subscriber`s (Differential Mode) circuit, the Hybrid telephone circuit would still sustain the supervisory (Common Mode) circuit."

That is certain. The common-mode is using the differential-mode wires ((the pair) in parallel anyway and the short-circuit has little effect on the common-mode because there is little common-mode voltage between the wires. No current flows between points of equal voltage, so the short has no effect when it occurs. You know all this from your balanced bridge example

All the common-mode voltage is between the pair and ground, or between the first pair and a second pair depending on the chosen application.

The principal cause of independence between modes in phone pairs, after balance has been established, is that every pair and every mode is supplied signal from a separate generator.

Such independence does not exist in our ham radio example. One and only one transmitter is supplying all the signals being considered, both the differential-mode and the common-mode signals.

This single source locks the signals together.

Best regards, Richard Harrison, KB5WZI

you definately are not to old!!!!! i was well over 50 before i got my
first
ticket. the state of the art has advanced tremendously in the past
decade,
radios that are relatively inexpensive offer features that were only
dreamed
of 20 years ago or were available on rigs that cost tens of thousands of
dollars.
there are new modes to have fun with as well. i see that you are in the
dallas/ftw
metro area, so am i. there are clubs here that cater to virtually any
interest
you may have in ham radio. go to the arrl site, http://www.arrl.org/ and
do a
bit of reading to catch up on what has been going on the past 15 - 20
years.

i can't speak for the rest of the ham community but speaking for myself,
HAM RADIO is a BLAST!!!

I have both...an A-3 and dipoles. If I am more successful with the dipoles
it is usually because I hear someone off the side or from an odd angle.
Listening for DX is so important. Often I'll hear someone on the dipole,
then switch to the beam after I figure out the direction.

If I had to choose I'd go with the dipoles. The bandwidth also provides you
with a little more flexibility frequency-wise.

Marvin,

Forget the balun. On 80 meters, where your antenna is resonant, the balun will cause a mismatch. The impedance will vary widely, into the thousands of ohms on other bands, which will not be handled properly by the balun. All you will be doing is generating a lot of heat in the balun and still have a high SWR on your transmission line which will result in even greater loss.

Feed the antenna with a balanced transmission line to your tuner and it will work fine on all bands.

Don - K2PMC

One would assume that the "gain" in the other half of the Universe (the half
found *below* that perfect, infinite ground plane) is effectively zero. On
average, it appears to all balance out.
```

> I have an 75m dipole that I couldnt get to prune to 6 meters (14th
> harmonic) ...

52/14 = 3.7+ MHz. But 14 is an *even* multiple of wavelengths so you
are feeding the dipole near a voltage maximum point (high impedance)
instead of near a current maximum point (low impedance). You would
need an odd multiple to get a low impedance. 52/13=4.000, 52/15=3.470
I can resonate my 80m dipole on 6m by varying the length of the
ladder-line.

Truthfully, I'd bet they have no idea what phase anything is.

This entire thing is clearly a technical hoax. Something someone just dreamed up and tried to snow people with technobabble using buzz phrases about Poynting.

They not only do not understand common mode and differential mode, they don't understand simple circuits like networks or baluns. With that in mind, we are supposed to believe they understand more complex things like radiation...or how to make measurements.

Have fun, but I'm afraid you are wasting your time taking advice from people who know less than most others do about what they invented.

According to Cecil (and Harrison) they are.

>If the sun went out - the power source vanished - would we both be
>affected? Of course.

And that is the logic...except for this...

In a system common mode and differential mode excitation does not even
have to come from the same source. So in this case, a star other than
the sun might be at work.

A better analogy George would be if you are on Earth, and Cecil is in
another solar system are your actions related or not related?

>But absent that event, it seems to me that my sphere
>of activities while possibly similar in some respects to yours - we both
>eat, sleep, etc. - are hardly related in a scientific sense.

Cecil and Harrison seem to think they are related.

>In the simple transmitting case, coax feed to a wire dipole antenna, it
>seems clear to me that the presence of common-mode current on the outer
>braid of a coax line must arise either from the division of current at the
>coax braid connection to the antenna in the absence of a balun or from its

There are other causes also. It could be a flaw in the transmission
line or connection to the generator, or another external source.

>In either event, the comparative impedances of the system elements involved
>play a central role in establishing the magnitude of the effects. Whether
>or not these impedances are known or can be known quantitatively is another
>matter. But clearly they exist, even if some may be zero and others
>semi-infinite.

Of course they exist, they just are not related. The common mode
impedance and even the velocity of propagation or phase differences
can be anything compared to differential mode.

I suspect the real truth is Cecil does not like that idea, because it
means his dipole scheme might not always result in low common mode

currents.I'm sure other than that he cares less what I think.

>The stronger the differential-mode power component, the more excitation is
>available for the ultimate production of common-mode current. Thus, any
>changes in the system which alter differential-mode operation and
>performance is likely to have some effect on the common-mode current as
>well.

If they come from a common source and you change the source. But I can
make changes in the system that INCREASE differential mode impedance
and they can reduce coupling to comon mode, increase coupling to
common mode, or not change it.

Call me a fool, but I think that shows they are unrelated effects as a
overall view of systems. Now we might find a particular system with an
effect that tracks between the two, but we can easily make it NOT
track with a small change.

The only thing common might be the generator, and even that does not
have to be so!

>1. Differential-mode operation and common-mode operation are related in
>some manner highly dependent upon system configuration.

Or they might be unrelated. You can not forget that possibility.

>2. They are both manifestations of the overall operation of the entire
>antenna system, not just the transmission line.

...and source. Don't forget that.

>3. An analytical solution to determine the relationship is probably neither

>also entirely possible that Change A may produce zero observable effect.
>The existence of either outcome neither proves nor disproves anyone's
>contention that the two are or are not "related."

They may either track, not change at all, or move opposite directions.
They may change at different rates and directions throughout a given
system that range from one extreme to the other.

I guess that means they are related, eh?

The real problem with sideways thinking that they are related is that
people leap to incorrect conclusions. Cecil and Harrison did that with
the balun, as do most people. People like to think a balun works

better at a low impedance differential mode point, when that isn't true. They like to think a balun always changes, or worse yet always reduces, common mode current. THAT is not true either.

It is much better and much less troublesome if we just admit that common mode behavior and differetial mode behavior of a system are based on two unrelated systems, and those system can have any relationship or even no relationship at all to each other.

Hence sticking a W2DU balun, or any other balun, in a system can increase problems, decrease problems, or not change a thing we might notice. There are many cases where adding a balun will actually increase feedline radiation.

You have to know the system, but short of that it is best by far to assume the common mode and differential modes are unrelated. Unless you are trying to sell a certain idea out of a traveling wagon show.

Off center feeding your 75m dipole by 4-6 feet would have little
effect on 75m operation and would allow you to find a current
maximum point, i.e. resonance on 6m.

Tom W8JI wrote:
> In a system common mode and differential mode excitation does not even
> have to come from the same source.

But for your original statement to be true, common mode and differential mode excitation must ALWAYS come from different sources. You said that common mode conditions and differential mode conditions are "NOT related". They often come from the same source so your statement is false.

If common mode conditions and differential mode conditions are ever related in even one system, your original statement is false. Would you like to revise your original statement?

If you had said it is possible for common mode conditions and differential mode conditions to be unrelated, or that common mode conditions and differential mode conditions are not always related, then nobody would have objected. But your statement with the capitalized "NOT" says they are *never* related and that is simply false. I have proved that they are indeed related in my three antenna systems. How can you rag on others for spreading false statements when you are doing the same thing?

You said that common mode and differential mode conditions are "NOT related". Sometimes they are related. That makes your statement false even if they are sometimes not related. All the mealy mouthing in the world is not going to change that fact. Your assertion that you were right about 'A', therefore you are right about everything, is the wishful thinking of an extremely immature individual and is not going to wash.

Yes Wayne, the OS-1 rate is computed at 30 Lb default value.

I shipped many boat vfh/loran antenna from VA to WA for $ 21.00
at UPS office and for $ 17.00 from our in house mail dept.

Still not too expensive, the US Post Office was about $ 5.00 less expensive.

Tom, you are trying to make 100 true statements to keep from admitting
that you made one false statement. Old trick, doesn't work. You can make
a million true statements but your false statement is still false. You
are trying to imply that you said the common mode conditions are not
necessarily related to the differential mode conditions. That's not what
you said. You said they are "NOT related" which, given the capitalization
of the word "NOT" for emphasis, means never related.

I said: The basic question is whether common mode conditions are related to
differential conditions (or not).

You said:
> Then the answer is no, they are not related.

You didn't say they are sometimes not related or not necessarily related. If
there exists even one antenna system where the common mode conditions are
related to the differential mode conditions, then your statement is false. It
is probably safe to say that the great majority of IN-34 detectable common mode
conditions existing in an antenna system when an amateur radio transmitter
is keyed are indeed related to the transmitter's differential output. It
is foolish in the extreme to argue that common mode conditions and differential
mode conditions generated by the same source are "NOT related" but that is
exactly what you are clinging to for dear life.

We can probably agee that common mode and differential mode currents share:

1. a generator
2. a wave period

While formulas describing the behavior of RF current seem to apply equally to both modes, I'm having a hard time envisioning how the variables within those formulas relate across modes so as to predict anything that might constitute a relationship (the exception being frequency).

For example, can anyone draw a mathematical relationship between differential and common-mode impedance on a transmission line? What is the relationship between velcoity factors? What is the phase relationship? Loss? Mutual coupling?

We know frequency is the same. We may even be safe in suggesting that amplitudes will track with proportionallity. But, what else can we predict with certainty every time?

Hi J.,
I've got another important question. If the gain of a monopole is
twice that of a free-space dipole, wouldn't the monopole's effective
area also be twice the dipole's? It may be new news if they are
arguing that the monopole violates reciprocity. Meanwhile, I'll have
to go back and look at the PDF. 73,

The main cost of putting in the conduit is the work of digging and
filling the trench. It's one of those jobs you only want to do once!

A few extra $$ spent on bigger pipe, and a second run, will be well
worth it if you ever have a problem or want to run more cables.
Although that 1-1/2" stuff may look plenty big, conduits fill up
faster than you think.

--

For the application described, I would prefer two smaller conduits to
a single large one, if cost or space didn't permit two large ones.
First reason is rendundancy in case of failure. Second reason is that
it's easier to pull cables in a conduit that has only a cable or two
in it.

And therefore are related in some manner, which disproves the assertion that they are "NOT related".

> While formulas describing the behavior of RF current seem to apply equally to
> both modes, I'm having a hard time envisioning how the variables within those
> formulas relate across modes so as to predict anything that might constitute a
> relationship (the exception being frequency).

I have already said they are unknown and unpredictable. That doesn't mean that they are "NOT related". Like the sun and planets, all one has to do is measure the relationships. Not knowing the relationship is not the same as being "NOT related" unless one believes that one's lack of knowledge controls the universe. Since when did lack of knowledge prove anything except lack of knowledge?

> For example, can anyone draw a mathematical relationship between differential
> and common-mode impedance on a transmission line? What is the relationship
> between velcoity factors? What is the phase relationship? Loss? Mutual
> coupling?

You have completely missed the crux of the argument, Rick. The only question is whether Tom's original statement is true or false. I can't locate the original statement but here is where he repeated it.
****
I said: The basic question is whether common mode conditions are related to differential conditions (or not). No tuner required. No movement required.

Tom said: Then the answer is no, they are not related.
****
He didn't say they don't have to be related or that they are sometimes unrelated. He made an absolute statement, "they are not related". If they are ever related in any way whatsoever in any system whatsoever, Tom's statement is false. He has thrown up a logical diversion in the past few days to try to make everyone believe that 100 true statements make up for one false statement. His ploy seems to have worked on some people.

> Why buy expensive tuners to achieve antenna match.

Good question! I build mine for very little money. I spent less than $20 to build a complete "Ultimate Transmatch" that has served me very well. Roller coil from a BC-375, Cardwell splitstator cap, ARC-5 transmitter padder cap. Some rotary switches and a built-in Monimatch. All housed in a BC-375 tuning unit case. Reduction verniers on the caps, nice black wrinkle finish. Selects 2 coax and 1 long wire antennas and up to 4 rigs.

> Build a GAMMA MATCH. Complete instructions $7.00.

Same info is in my $2 hamfest-special ARRL Handbook.

> See www.tiller.net

I went there. What's interesting is that you don't mention the fact that the gamma match will only do its thing on one band. In some cases it will only work over part of the band.

Gammas are great for monoband Yagis or shunt-feeding a tower on 160 or 80. There are better solutions for other situations.

Transmatches are neither expensive nor difficult to build. Hams buy them because they prefer to spend money rather than time.

Tom, W8JI has changed his story from NOT, and NEVER, to don`t have to be. He does not admit that NOT and NEVER were blatantly wrong.

In Tom`s June 28, 11:29am posting, the oldest in this thread displayed for me, Tom says:
"Far field is a DISTANCE problem, not a PHASE problem."

Were this "always" true, how would gain antennas work? It`s the distance and phase of signal contributions at a far-field point that determine the signal.

In the same posting, Tom says:
"Nonsense. The bulk of efficiency loss in any small antenna is almost always due to cancelling the reactance in the antenna."

Should have at least replaced "any" with "a".

Cancelling the reactance in the antenna does not cause inefficiency. Adding a coil`s resistance causes inefficiency.

Tom also ignored another class of small antennas in his false statement. The small loop has its reactance cancelled by a capacitor which can have low loss.

Some Tomisms are conceptually wrong, as is:
"Farfield---not a PHASE problem."

Some Tomisms are mistakes in expression, as:
"---loss in any small antenna is almost always due to cancelling the reactance in the antenna."
The idea was right, but the statement is false.

How is the newcomer to differentiate?

Best regards, Richard Harrison, KB5WZI

Hmmm, I have not seen any disagreement for about a week relating to anything technical. No issues about where the electrons go, no arguments about how waves behave, no real issues about balance, the effect of ground, the phase of the moon (Oops, strike that, we did see a discourse on celestial physics), or anything else technical.

This thread is now reduced to:

1. A subtle semantic issue over the exact meaning of "not", or perhaps "NOT!!!!"

2. Pride.

Is there anything left in this thread that relates to antennas?

73,
Gene

Rick, K1BQ wrote:
"But what else can we predict with certainty every time?"

Put a dipole in free space connected to a parallel-line transmission line. You don`t take the feedline away at 90 degress, so that you produce coupling in this particular case. What is the coupling between feedline and the antenna?

First, you need to know the angle between the feedline and antenna before beginning to calculate coupling.

More likely, in a real world antenna and feedline, you would measure the common-mode coupling after your antenna set-up.

Broadcast stations measure the coupling between antenna array elements (towers) as described in earlier postings. You can measure common-mode coupling the same way.

Broadcast stations have good estimates of anticipated coupling based upon massive experience but it must be measured as built.

Once finalized, the coupling between towers in a directional array does not normally change. The array works as designed and built year after year.

Best regards, Richard Harrison, KB5WZI

There are lots of fun things to do these days in amateur radio.
Whatever floats your boat, practically.

As to being too old, I was 13 when I got bit by the bug. Didn't know
anybody and neither did my folks. I was left hanging until I was nearly
40. Then found an Elmer who got me going and within a year or so I had
gotten my Extra Class ticket (including the 20 wpm test).

Nowadays the code is easy to pass, but I'm no longer sure I could pass
the written test.

Good luck and 73

Hi Cecil,

On the one hand you insist that Richard's example is out of context,
so to speak, and then you insist that I provide another, that would
also run the risk of being out of context, so to speak. This is all a
patchwork quilt being unraveled as you reject each suggestion that
does not conform to your impression of what constitutes a proof of
your thesis.

I would suggest that you simply resolve the current context with a
simple rendering into the obvious bridge configuration that Richard
already responded to. None of this is so demanding nor technically
challenging is it?

Dunno...Thats up to you. I think I had more "fun" back when I first started. "as WD5CJL". I was pretty primitive back in those days with crappy receivers and a simple homebrew xmtr. Now that I'm all fancied out with good rigs, antennas, ad nausium, I actually find operating pretty boring now. No real challenge at all. It's like CB with a fancier name and gear. Well, let me take that back...I know some cb'ers with better gear than I have.. As far as having fun on the air, I still prefer CW over other modes. At least it gives me something more to do, rather than just yik yakking by voice or pecking at keys. And I get plenty enough key pecking here on the net. MK

>Best regards, Richard Harrison, KB5WZI

Hi Richard,

This is simply framing the question to match the answer. In fact
Common Mode on any system is stimulated by every nearby source of
radiation and this is a natural consequence of living in a real world.
As such there are more contributors to the Common Mode than the single
myopic focus that is straining to reject them. And further, those
currents and potentials are wholly unrelated except by arguers'
inflexibility or their introduction of divine intervention to support
a specific thesis as a generality. The correlations are (as Jeff
offers) obvious on the face of it; however, the arguments beyond that
are specious.

I am not interested in the folderol about applications of absolutisms
where the contrarians employ absolutisms in their offensive. Such
argument that has evolved from those conflicts is simple a battle of
egos. If I were to weigh in on the discussion with my own
observations of the corruption of language (having done so
tangentially in the sentence introducing this paragraph), few would
come away with less than tatters. There are none here that have any
argument but with language and to their embarrassment they dress it as
technical distinctions. That is outright baloney on both sides.

Richard, you have attended the technical distinction of the Common of
the Common Mode, as has Jeff by numerous examples. I am not impressed
with a thesis that ignores these (more than probable supporting)
examples out of fear of losing rhetorical leverage.

I have offered Cecil that he could be right if he but provide a simple
answer to his own "context" to resolve if any errors remain in his
thesis (and Tom has demonstrated errors to which Cecil has allowed).
Barring that, I have to respond to Cecil with:
>Given you have no response to where the
>Common of the Common Mode resides, I must stand aside to withhold
>committing to your thesis until the revelation of this simple and

>(dare I say it?) common consideration.

Hi Rick,

You are asking for more than is necessary. One could endeavor to
answer the minutia, and in doing so come up with an absolute answer;
but it is not necessary to know the actual values of:
R1 / R2 = R3 / R4
to observe a relationship that is manifest in the equation.

Scrimmaging for the actual value of R1, its impressed phase (if
complex and hence appropriately called X1), its genesis (velocity
factor or such), the potential it sees or the current is supports is
all noise to the issue of "relationship." The only argument these
measures could resolve is the magnitude of relationship (the
relationship will persist in spite of the measure).

>"NOT" is one of the few English words that has an exact meaning.

Hi Cecil,

As I offered in other writing, the engagement in dialectic of language
is bound to lead to contradiction. There is nothing exact about
language, "not" even your statement above.

The Oxford English Dictionary has four (4) entries for this word of
which the first three offer:
"to clip or cut short (the hair or beard)"
"close cropped, short haired"
"of sheep or cattle, hornless"
and finally your (I presume) usage:
"the ordinary adverb of negation"

Relying on language as a critical element of proof is poor proof
indeed. Even if we dismiss the first three definitions, there is
always the colloquial usage which suggests that absolute application
is not always meant nor to be taken.

Tom`s obfuscating again.

The relation, Z = E / I, is true and exists no matter if you change E&I to make its value large or small.

You can shift the ratio in a gear box, but that does not make wheel RPM independent of engine RPM.

The fact that flywheel rotation and RPM of the tires are changed with respect to each other does not make them unrelated.

Same with common-mode coupled to differential-mode. Changing the coupling does not make them unrelated.

Best regards, Richard Harrison, KB5WZI

Richard Clark wrote:
"I am not impressed with a thesis that ignores these (more than probable supporting) examples out of fear of losing rhetorical leverage."

No fear here. Try to keep the argument simple, but not too simple, that`s all.

At Richard Clark`s urging, I offer a new thought which includes his bridge idea and applies to modes for a single signal or multi-source signals.

Suppose we have a dipole and feedline under Jeff`s powerline. A measure of imbalance in this system may be the differential signal from the system at 50/60 Hz.

The wavelength of the power frequency is so long that the current and magnitude everywhere along the powerline near our antenna system is practically the same.

So, any powerline pickup on the antenna system is due to imbalance. This is hard to quantify, but may be not so hard to minimize by adjusting the balance.

This is extraneous to the argument of the differential-mode is related to the common mode, yes or no.

Bewst regards, Richard harrison, KB5WZI

None of this is technically challenging enough to require a bridge.
It only takes one example to prove that Tom's statement is wrong
and I have provided that example with my code practice oscillator
that allows Morse code to be read by detecting common mode currents.

I have provided all the proof that is needed, Richard. I don't feel
link wasting my time on techno-bafflegab. All it takes is one example
where common mode conditions are related to differential mode
conditions to prove that Tom's statement is wrong. I have already
provided numerous examples. In particular, you can read my Morse
code from a Morse code oscillator triggered by my common mode
current detector. You may call that "NOT related" but you would
be wrong.

Hi Richard,

Your comments reveal the danger of myopic discussion. Common Mode
issues are not confined to those that give rise to an expected
problem. For example you go to describe Jeff's condition of the
overhead powerlines and unnecessarily embellish with
frequency/wavelength.

This external stimulus, while not obviously related to the frequency
of operation (and in fact off by many orders of magnitude) does not
diminish the danger posed to the system (and I am not speaking of a
wire falling to the antenna and roasting the operator). The danger of
this configuration is that the front end could conceivably become
overloaded even in the face of input filtering AND with perfect

balance maintained such that some would reject the notion of interference. This is due in large part to the fact that any balanced system eventually becomes unbalanced by design within the service equipment. The induction from overhead wires may be balanced at the antenna, and yet if there is ANY connection to ground (even capacitively), those same currents will combine at the most inopportune junction that was not designed with inordinate care. Common Mode problems of this nature are far more commonplace than the issue of self stimulated Common Mode problems. Even though this argument confines itself to reception, the induction of Common Mode effects into the transmitter follow similar paths.

One example found in commercial broadcasting (and I am sure you can offer many compelling tales) lies in nearby transmitters inducing currents that mix with the intended currents at poor joints and create transmission spurs (or worse, cascade back into the amplification path). This is just as threatening with a completely balanced system (naively presumed to be immune from Common Modality). There are limits to protection by system balance and are often spoke of in terms of compliance (not the legal term, but rather the ability of a design to provide enough current/voltage to overcome and balance interfering signals).

Common Mode rejection, especially at frequencies above 1 MHz are extremely difficult to control and are best battled at the source. This statement's most compelling application is with the W2DU current balun. Ignorance or rejection of consideration of where the Common of the Common Mode resides leads to such problems.

As for this discussion being "extraneous" to the topic, the topic was resolved long ago and the "arguments" have been ones of language and ego. I care not for the outcome of the "arguments" and only wish to impart the importance of the subject of Common Mode which is so frequently mis-understood and often mis-applied.

Consider a single wire, 1/2WL long, with no transmission line. It is resonant on approximately 468/Length and relatively high currents will flow in the wire from signals picked out of the air on that frequency. Now install an insulator in the middle. It will no longer be resonant on that frequency. It instead has been converted to two 1/2WL wires resonant on approximately double the original frequency.

Hello Bill, Alan and 'Doc,

The authors of that paper are well known and (I think) very well respected.
I believe that one or both of them wrote the original NEC implementation.
It would be interesting if they are not correct, or if the results are true
and a new finding.

I await with baited breath further discussions on the contents of that
report.

I'm using a previously-mentioned .pdf file for bait.

My intentions are pure. If that report had been dated 1950 I wouldn't have given it a second glance. It seems like a rather fundamental topic to be brought forth in the late-1990's. Amazing (most likely).

If you've done any 2.4 GHz printed circuit board work it'll be a piece of cake. Look at page 12 of this pdf file:
http://www.analog.com/productSelection/pdf/AD8314_a.pdf

Above the AD8314 is a Murata directional coupler. Connect your antenna connector via 50 ohm stripline to pin 4 and the radio connector the same way to pin 8. Use PIN diodes to switch the input of the AD8314 between pins 1 and 5 on the directional coupler (1 for forward power/calibration, 5 for reflected power/SWR.) Connect 50 ohm resistors between pin 7 and ground and pin 3 and ground.

For less than $20 in parts you can build a VERY fine instrument!

It was the one where Cartman was kidnapped by aliens who "probed" him, then released him the next morning. At school, he started farting, and flames were shooting out of his backside - he even caught his cat on fire. Then the kids were out trying to figure out how to get Kyle's brother back from the same aliens, and Cartman farted again, and a huge antenna pops out from his behind to call the aliens back to Earth.

Strange show indeed, but I thought it was appropriate to the thread! 8^)

Sweeps are like pipe "elbows", except that the radius of curvature is much
greater. They look like pieces of bent pipe. Much easier for the cables to make
a bend of large radius. Coax can be damaged if bent too sharply, or if pulled
over a sharp edge.

The availability of sweeps is one reason to bury conduit rather than
plumbing-type pipe.

I am interrupting my reading of Richard Clark`s posting:
"For example you go to describe Jeff`s condition of the overhead
powerlines and unnecessarily embellish with frequency/ wavelength."

Postings in this thread reveal primative understanding indeed of some
electrical princiiples by some participants. So, I differ with Richard
Clark. In my opinion it`s no embellishment to point out that the 50/60
Hz magnitude and phase are a constant in the antenna`s environment.
Otherwise, you could not expect cancellation in a balanced antenna
system of the 50/60 Hz. You know it and I know it, but from what I`ve
seen Tom prtobably does not know it.

Best regards, Richard Harrison, KB5WZI

A different type of advice for AD9E -
Don't design an antenna and then try to find a place for it (how high do the ends of an inverted vee have to be?). Instead put your antenna wherever it is most convenient for YOU, in YOUR situation. It will work. Don't worry about optimizing things, you aren't going to have an optimum antenna situation. Remember this - "The toughest thing to do is to get an antenna to NOT radiate!"
I know a guy in a close neighborhood with 3 hf antennas, a dipole in the attic, a wire from the roof down to one of those screens over a swimming pool, and a vertical next to a tree. The interesting thing about his situation is that his neighbors (and I mean these houses are CLOSE together) do not know he has any antennas!

I resumed reading Richard Clark`s posting and he wrote:
"---nearby transmitters inducing currents that mix with intended currents at poor joints and create transmission spurs---."

This is more likely a receiving antenna problem because there the relative strengths of the mixed signals is more competitive. It`s rare in a transmitting antenna because the received signal is very weak as compared with the transmitted signal.

I`ll repeat a story I told on this newsgroup some time ago. I weorked at a 790 KHz station located about 15 miles from a 740 KHz 50 KW station. Mornings when I fired up the 790 KHz station, I often could faintly hear the modulation of the 740 KHz station in the monitor speaker. Our antenna picked up the 740 KHz signal and our final amplifier dutifully mixed it with the 790 KHz carrier.

The 740 KHz audio was more than 50 db down and the r-f intermodulation products were also within limits, so we ignored the mixing.

Best regards, Richard Harrison, KB5WZI

I have 3 in PVC and in it right now I have 4 RG8 cables and a rotor cable. It is extremely, and I mean extremely hard to pull the last cable through. 4 inch is the way to go. Why not? The cost is next to nothing, the labor is no more either.
Two 4 inch pipes would be ok. Once that concrete is poured you can't redo it.
When the guy said to use sweeps he meant your 90 degree turns should be done with pieces called "sweep" They have a more gentle turn.

Forget 1.5 inch pipe. Don't for a minute even consider it.

And before you pour the concrete also make sure you bring out a connection from the rebar for grounding.

Hi Jim,
Thanks, I did not know that. Wouldn't it be easier to use the gray
plastic pipe electricians heat to bend? You could avoid all sharp
bends and a lot of joints that way. I also saw a home made plug for a
pipe. It was made out of 1" hardwood cut to a circle that when cut
into fourths and fit back together fit into the end of the pipe.
Before cutting into fourths the guy drilled the holes he thought he
would need on the cutting lines so when he fit the pieces back
together over the coax, they fit snug. Extra holes were filled with
bottle corks for future use.

Message-ID: <20020706010246.15533.00002671@mb-fx.aol.com>
Source record: 139272

I have read various articles on horizontal loops and still have a few questions. First let me say that my interest was peaked by several notes i have read from field day groups exclaiming how pleased they were with the horizontal loop at ONLY 20FT.

I got a copy of EZNEC DEMO and played with various size loops and heights. I was surprised to see some noteable gain figures using an 80m loop at 20ft height on 20m and above but more significantly there were some nice lobe patterns which see like they would accomodate the NW operations.

Elevating or enlarging the loop then developed patterns with multi lobes at various takeoff angles and as you approached 15m and above with very large loops (800ft+)--patterns which look like avocadoes.

I am not too sure if my modeling was too crude to be of value. Have any of you used horizontal loops and what was you rexperiences. In particular any one use an 80m loop at about 20ft?

Alan,
I couldn't swear to my loop being at exactly 20 feet, but the majority of it is pretty close to that (if not a bit lower in spots). It's a 1 wave length 80 meter loop, very close to about 255-260 feet. In sort of a rectangular shape. On 80 meters it behaves much as a dipole does at the same height. Maybe a little quieter, but not a whole lot. On 40 meters, well, it's not the best in the world. on 20 meters and 17 meters, it isn't bad. Just depends on where the lobes fall, Europe seems to be in one of the lobes, as well as most of South America. Australia is also in one of the lobes, they are loud.
There are also directions/places that seem to have disappeared too, it isn't all milk and honey. It doesn't seem to like 15 or 10 meters all that much, at least I can't get a 1:1 SWR on either band. I can understand 15 meters not being the best, but I find not being able to get a good match on 10 meters a bit strange. Oh well, I don't hear much on 10 meters with two other 10 meter antennas either. Who knows.
I'm very happy with how my loop works. It isn't a 'miracle' antenna, but it works just about everything I care about listening to. Is that what you're looking for about loops?

PVC electrical conduit is the gray stuff. If you can bend it without weakening
or kinking, go right ahead! The ready-made sweeps are not expensive.

>You could avoid all sharp
>bends and a lot of joints that way.

Joints aren't much of a probelm if they're smooth, but sharp bends are a
disaster.

Great idea!

Another way to do the job is to terminate the conduit in waterproof boxes.

--

One of the things I used to be involved in professionally was burying cables
that crossed roads. We used nothing but 4 inch galvanized threaded conduit,
which came in 10 foot lengths. Heavy stuff! We'd usually put in two pipes even
if the cables would fit in one, "just in case".

With those assumptions, the answer is yes, and 1.5:1 is a perfectly
acceptable SWR even without an antenna tuner.

> such a scurrilous term.

From the IEEE Dictionary: "common-mode voltage - The voltage common to
all conductors of a group as measured between that group at a given
location and an arbitrary reference (usually earth)."

So given the two ladder-line wires, common mode current is the current
that is in phase in the two wires. Differential mode current is the
current that is 180 degrees out of phase in the two wires.

Also one more proof that common mode is related to differential mode.
When I was in high school, I had a 66 ft dipole fed with about 50 ft
of coax used on 40m with no choke/balun. 50 ft of coax is near a
worst case length for common mode problems on 40m. My Globe Scout
was not grounded. I burned a hole in my lip from touching the metal
microphone. Does anyone not know whether that happened during receive
or during transmit?

Look here for the manual. If you can't find it, e-mail them. The on-line manuals DO NOT have schematics, but most all of MFJ's antenna tuners are "T" matches and rather easy to figure out.

And do as one reply suggested, invest in some good literature. I venture to say that 90% of the questions posted on this newsgroup could be answered by reading the ARRL Handbook and/or Antenna Book.

> > Or does this defeat the whole purpose of using ladder line?
>

You can transform the impedance at the junction by using varying lengths of coax, similar to Cecil transforming his feed impedance with varying lengths of ladder line for different bands. If it works with ladder line, it works with coax. A half wave length of transmission line reflects, at the far end, the impedance seen at the input end. Along its length the impedance varies from the input impedance to a maximum high value at the quarterwave point, then drops to the feedline input value at the far end.
You can find the value needed to match the ladderline with a bit of experimentation. You don't even have to know what the ladderline impedance is at the junction-that will depend on its 1ength and the frequency. Be aware that you can use LESS than 1/4 wave length since the impedance repeats in reverse past the quarterwave point. In other words it goes up till it gets to the quarterwave point then starts back down and is again at the same value as the input when you get to the 1/2 wave point. Think of it as half a sine wave.
It may take some serious cut and try, but you can do it. Don't bother to install coax connectors until you have found the right lengths for the bands of interest.... just cut and twist the ends to try it.
When I get to where I can use ladderline I plan to cut several pieces of RG58 to various lengths, from 5 feet to 50 feet, probably about 8 pieces total. That should allow for lots of matching possibilities, and coax stores much easier that ladderline, especially when in use, and it isn't affected in operation by external objects or fields. You can run it beside metal or whatever without problems.

You'll need to arrange a switch to change the coax to match the band or just change it manually.

>location and an arbitrary reference (usually earth)."

This conforms to what I offered some weeks back, glad to see it
confirmed in some manner by the IEEE. In light of now knowing what
the term Common Mode means, the question is, and remains, is the
Common of your Common Mode artifact earth? If it is not, what is it?
Or does this simple question remain to cause you to
> have no idea what you are asking for

Anticipating that this one and only question is such a killer, I will
offer variants - unnecessarily elaborated, but that seems to be what
attracts attention and response. - sigh -

Let me boil it down even further. You measure a current a la
>Here is the context, published by myself many days ago.
>XMTR---x---coax-----choke---1/2WL ladder-line---well balanced 1/2WL dipole
>
>Common mode measured at 'x'.

I presume that given the less than full context, that what you mean by
the last statement is current (since Common Mode is an encompassing
term that covers both current and potential).

Your thesis is that XMTR is the source of Common Mode current, my
second question is:
Where is the current flowing toward at any point in its cycle
(choose your own point except at the zero crossing of course)?

Third question:
Taking that same point in its cycle, can you describe the
complete path of current flow? (answer must conform to
standard Kirchhoff laws, consult IEEE dictionary if necessary)

you may choose to skip that tough nut, and answer this fourth question
for partial credit:
Once the Common Mode current (at that same point in its cycle)
reaches either the XMTR or dipole, how does it return to its
source? (the answer to how, once again, requires the description
of the path - yes I am aware of the irony)

These are all trivial considerations taught in Basic Electricity and
Electronics Preparatory (BEEP School for vets in the audience)
training to technicians in the Navy BEFORE they can proceed to the
matter of transistors, tubes, amplifiers, radios and transmitters.

If you cannot describe the Common of Common Mode, it is likely because
you do not have a complete picture of the entire circuit. Making
appeals and generalizations to having shown its effect without being
able to describe the circuit is at best one of luck and offering it as
a "proof" is no proof at all.

There may be some in the readership that recoil in Angst at this and
offer the dog-ate-my-homework answer:
"It just goes back and forth in the same place because it is
AC and that is the way AC current flows."
I failed several many students for such obtuseness - such quality of
technician is dead weight at sea where there is no Radio Shack to pull
into to make the Radar work (or in the fashion of equipment operators,
to buy a replacement).

With tongue planted firmly in cheek, do I need to offer the fraudtenna
style of
$1000 COMMON MODE CHALLENGE
to get an answer to these questions? ;-)

> ladder line, it works with coax.

Well, as they say on the Hertz commercial, "Not exactly!" Here's why:

In order to perform impedance transformation using the transmission
line, we need an SWR higher than 1:1. Using 50 ohm coax, it is impossible
to transform an SWR higher than 1:1 to 50 ohms with a single series section
transformer. (Hint: That 50 ohm target is in the exact center of a 50 ohm
Smith Chart.) With an SWR of 1.5:1, you can use 75 ohm coax to transform
the resonant impedance to 50 ohms but it can only be done with a resistance
equal to 75*1.5 = 112.5 ohms. With an SWR of 1.84:1, you can use 92 ohm coax
to transform the resonant impedance to 50 ohms but it can only be done
with a resistance equal to 92*1.84 = 169 ohms. Both of these limits are too
low to be very useful with non-resonant length dipoles.

If the SWR on 50 ohm coax is 10:1, the transformed impedance at resonance
will be 50/10 = 5 ohms, a relatively lossy condition for the average
antenna tuner. It's an attractive idea but it doesn't work very well
in reality because it leaves you with an additional matching problem.

However, using 400 ohm ladder-line with an SWR of 8:1 can transform the
resonant feedline impedance to 40 ohms for which an antenna tuner is
not even needed. Using 600 ohm open-wire line with an SWR of 12:1, the
resonant feedline impedance can be transformed to a perfect 50 ohms.

Moral: The characteristic impedance of a series section transformer
needs to be different from the target impedance of 50 ohms.

I normally try to stay out of these "how many angels can dance on the head of a pin" discussions...

The argument to date can be equated to "How does DC relate to AC"

Cam says "turn off the AC switch and the DC output goes away, ergo I am right".

Tom says "You have to measure the particular system and that relationship can not be applied to a different system, so no relationship exists if I change the DC output voltage regulator, ergo I win"

Cam gets out his copy of "Games People Play", turns to the chapter "Now I've got you - you son of a bitch" and proceeds to play.

Each has crafted his argument to a single situation and both are right for the conditions stated.

Does this add to the body of knowledge of anything? Nope! but it makes an interesting debate on what the meaning of IS is...

To keep from reinventing the wheel, please reference Fig. 1 - (Imbalance
caused by another path to ground from only one side of the dipole) and
Fig. 4 - (When the rig is connected to ground, a third conductor in parallel
with the right side of the feedline is introduced. This causes an imbalance
in both coaxial cable and twin lead feed lines) in Roy's article in the ARRL
Antenna Compendium Vol. 1, titled, "Baluns: What They Do And How They Do It".

This antenna was described in the 1955 ARRL Handbook and I used it in
1956 with a Heathkit air-core balun. It worked well on all HF
amateur bands existing at the time. If one draws out the current waves
and voltage waves for an off-center-fed dipole, why this approach works
will become readily apparent. The ratio of voltage to current at the
feedpoint is somewhat similar for all the harmonically related bands.

According to some on this newsgroup, the SWR is "NOT related" and must
be measured to be known with any accuracy. (The Devil made me do it.)

> including warc.

That's an interesting assertion. Here's what EZNEC sez:

3.7 MHz 115 +j0 ohms
7.3 MHz 293 + j0 ohms
10.125 MHz 391 - j872 ohms
14.2 MHz 246 - j445 ohms
18.14 MHz 333 - j 136 ohms
21.3 MHz 501 - j428 ohms
24.95 MHz 376 - j464 ohms
28.3 MHz 479 - j668 ohms

What is the magic length and height of an 80m loop such as you describe?

> report.

Hi J.,
Geez, you didn't have to bait your breath.

After looking at the actual report, I suspect the authors put it out
to cover some disputed results coming out of MiniNECPro.

The authors derive theoretical expressions for the coupling between 2
antennas given as the ratio of the transmit power to the received
power. These expressions are functions of the free space gain and the
gains of the transmit and receive antennas. They then use these
expressions to compute the coupling for 2 identical dipoles that are
very far apart. They proceed to use MiniNECPro to verify the theory
(?) and find that the 2 values agree.

Next, they use the expressions to compute the coupling for 2 monopoles
that are
very far apart. The basis for their analysis is a value of 5.16 dBi
for
the gain of a monopole on an infinite ground plane. They again use
MiniNECPro to
verify the expressions (?) and find that the theoretical coupling is 6
dB greater
than the MiniNECPro value. The authors apparently take the MiniNECPro
value as being the correct one.

Rather than conclude that there is a problem with MiniNECPro, or that
there might be a problem with a 5.1 dBi gain for a monopole, they
proceed to change the theory by re-defining the effective aperture for
the receiving monopole. Their claim is that the receiving monopole has
an effective aperture that is one-fourth that for a dipole. The usual
eqn for effective aperture is G(lambda^2/4pi), this would be for a
dipole. Their new "correct" eqn for a monopole is G(lambda^2/16pi).
Note the 4 fudge factor in the denominator.

Like I say, I suspect the authors put the report out in 1997 to gloss over some discrepancies between theory and MiniNECPro. Maybe the intent was to provide a method for which engineers computing received power would get results agreeing with the model's. If there was a discrepancy, I would think it'd be better to look at MiniNECPro as the source rather than theory. 73,
Bill N3WK

The gray "plastic" pipe the electricians on the sites use is made to
be "bent" for curves and arcs. Never saw them bend it in a 90 though.
Here in WI that's mostly what I see them use, when they are laying it
out before pouring the concrete floors.

Given its height of 7.2 mtrs, its very much a compromise antenna. I don't know how much it is, but you might be better off with a Butternut HF2V. The latter covers 80 and 40 (very narrow on 80) and has optional add-on kits for 160 or 30mtrs.
Any elecrtically quarter wave vertical requires a good radial system.

I think it is a very important report either way. If there is such a fundamental discrepancy in 1997, that is big news. If the report is wrong, that is big news too. I'm hoping that some of the regulars here will dig in to the report and come to a consensus.

Choose one:
-Fundamental antenna theory was wrong until 1997.
-Mini-NEC is wrong even now.

Exciting. Shall we take a vote ? (joking)

>1956 with a Heathkit air-core balun.

Not the same thing, Cecil.

The antenna you used was probably an OCF single dipole. The antennas described in the cq-DL articles and in the 1990 QST article are double-dipoles (four wires, each a different length). The double-dipole OCF antenna appears to have originated in Germany in the early 1980s (cq-DL articles from about 1983).

> It worked well on all HF

Even 15 meters?

>If one draws out the current waves
>and voltage waves for an off-center-fed dipole, why this approach works
>will become readily apparent. The ratio of voltage to current at the
>feedpoint is somewhat similar for all the harmonically related bands.

The unbalanced nature of the antenna may result in common mode transmission line currents in some cases, too.

Why on earth would we be even thinking about matching it if not?

Using 50 ohm coax, it is impossible
> to transform an SWR higher than 1:1 to 50 ohms with a single series section
> transformer.

So you're saying that the well known properties of a halfwave line are
not what the authorititave sources and books say? These properties of a
halfwave transmission line are subject to all your analysis? I guess I
missed all that in the ARRL antenna manual.

(Hint: That 50 ohm target is in the exact center of a 50 ohm
> Smith Chart.) With an SWR of 1.5:1, you can use 75 ohm coax to transform
> the resonant impedance to 50 ohms but it can only be done with a resistance
> equal to 75*1.5 = 112.5 ohms. With an SWR of 1.84:1, you can use 92 ohm coax
> to transform the resonant impedance to 50 ohms but it can only be done

> low to be very useful with non-resonant length dipoles.

You do as you wish, but I never would have a need to attempt a better
match than 1.5:1, even 2:1.

If there was no SWR involved, why would we be attempting to match
impedances to rid ourselves of most of it? I can see why it might
require one to cut the ladderline to a certain nonresonant length on any
of the bands in question.

Maybe you have all this figured out to the 5th decimal place, but for me, anything less than 2:1 is useable. I will probably try the plan I outlined on 20 meters before long. We'll see it it works. So far I'm not persuaded that it won't.

Hi group:

I took some photos of a 150 foot American Tower antenna in White City, Oregon and put them on the Internet in an album titled, "Amer. Tower's White City Tower" at the URL:

http://groups.msn.com/AlsPhotographs/amertowerswhitecitytower.msnw

I'm curious. What type of antenna is this? I suspect it's for cellular telephone service but I'm not sure.

If you visit the American Tower website, they give some information about the tower at the URL:

http://www.americantower.com/OASISPublic/SitePublicPagesADO/SiteBrochure.asp?lngSiteID=11818&lngTowerID=-1&txtCaption=Brochure

I look forward to your comments and I hope that you enjoy my photos.

Assume you have a folded dipole with a 300 ohm feedpoint. You are feeding it
with 50 ohm coax so it has an SWR of 6:1. What length do you make the 50 ohm
coax transmission line to achieve a transformation to 50 ohms at the transmitter?

That's an entirely different use and definition of the word "related".
My computer bus doesn't have wheels either.

In the context of common mode to differential mode, what else could "NOT
related" mean? "Common mode conditions are NOT related to differential mode
conditions" is pretty clear. If they are sometimes related, why would he say
"NOT related"?

Actually a balun is perfectly fine, you just should not use a voltage
balun. Voltage baluns (like most 4:1 baluns) do not handle wide
impedance ranges very well.

A choke or current balun is the preferred type of balun, and does not
introduce noticeable loss into the system.

All of my ladder line fed antennas use choke baluns on the outputs of
normal T networks. They actually work much better than old KW Johnson
Matchboxes I used to use.

I'm currently in the process of putting up a antenna tower and was looking for suggestions on what antenna to put on it. The tower is a 50' Rohn 25G. I have an Alliance HD73 rotor. I've looked at the lightning bolt HF quad. wwww.lightningboltantennas.com and the Tennadyne T6 Log Periodic. $400 is going to be my maximum I'm going to be able to spend so I'd like to keep all suggestions in that price range. Thanks for your time.

Those look like PCS antennas, but they could be late model cellular. Go to:

http://gullfoss2.fcc.gov/cgi-bin/ws.exe/genmen/index.hts

and walk through the forms with the site location. That will show who is licensed at that site and what frequencies they are on.

American Tower bought many of the defunct ATT microwave towers all over the country, and found that a lot of them were unsuitable for Cellular or PCS applications, and are selling them to Hams and others for reasonable prices. There is a big square 200 foot tower on the next hill from me which I could afford, but the local taxing district thinks it is worth about 10 times what it is, and the taxes would be unbearable. Of course, the 18,000 square foot two story blast proof building may also enter into that equation.

>Are you really going to support the assertion that "common mode conditions
>and differential mode conditions are NOT related", i.e. never related????

Hi Cecil,

I never said the relationship of some parameters of common mode and differential mode in a system can not have interactions in a particular system.

What I have said, time and time again, is common mode impedance (or voltage, or current) and operation is not related to differential mode impedance or operation, and it is a MISTAKE to assume they are directly related.

As a matter of fact, in a reply to a specific system where someone stuck a balun at at point with low differential impedance, and where everyone concluded the balun should have an effect or be effective, I pointed out the modes were not related. You and Harrison felt obligated to turn the whole topic to a long meaningless argument about the word "not".

All of this is a waste of time, and leads nowhere. Most people in this thread, after some thought, understand common mode is a different mode than differential mode operation, and they are not related in any fixed manner.

I think what is really important is not that you agree with me, like me, or respect me...but that we all do the best we can to help others understand systems.

When wanting to be right gets in the way of helping people, this newsgroup has no usefulness to anyone except perhaps horse's asses who like to argue just to argue.

My goal was to get rid of the common but silly notion that a low differental mode impedance means a choke balun will "work good", and a high differental mode impedance will make balancing the system or energy transfer a problem. I felt, in order to do that, it was necessary to stop the sideways thinking that a given action or change in differental mode operation results in a change...or worse yet a defined change.....in common mode operation.

In trying to get that into one sentence, the best I can come up with is to say "common mode impedance is not related to differential mode impedance".

Why not take a deep breath, and think about what tripped you up on the tuner? Clearly, it was because you (like most people) assume a low differential-mode impedance means the common mode impedance or excitation is low...and a choke balun will "work better".

How would you, in one sentence, tell people that common mode impedance is not related to differetial mode impedance, so they don't make silly assumptions about baluns? that is the goal, not arguing about the word "not".

Any one else have an idea, in case Cecil elects to not help others with this problem?

Please, minimal bafflegab. How do we tell people the differential mode impedance or behavior has nothing directly to do with common mode, and picking a favorable parameter for one has nothing to do with the other being changed the same favorable way?

Richard Clark wrote:
"I am not asking for proof."

My dictionary says the word "relate" is to tell or associate.

When the sun appears, it not only illuminates fully exposed sites, it also brightens the gloom of shady spots.

The sun`s indirect illumination under the shade depends on its brilliance nearby in the open. It isn`t direct radiation in the shade, but illumination in the shade is related.

With enough data collection regarding the relationship of direct sunlight nearby and the resulting illumination in the shade you could construct tables which allow you to make pretty good predictions of illumination in the shade from sunlight in the open nearby. Of course drought could kill the grass and change reflectivity of light into the shade. That would not be caused by loss of relationship between open space and shade, it just reflects a change in the value of the relationship of light in the two locations.

The same sort of relationship exists between differential-mode signals and the common-mode signals which imbalance in the differential-mode produces. Balance is the only thing that usually undoes the relation between differential-mode and common-mode. In the single-signal case we discussed, if you don`t have any imbalance, you don`t have any common-mode to relate to.

Best regards, Richard Harrison, KB5WZI

At the antenna. With real-world coax, the SWR will gradually decrease as
we move towards the transmitter.

Oh, I think something on the order of the circumference of the Earth
should easily do it, close enough for practical purposes.

(Quoting CAM, "The devil made me do it.")

Source record: 139240

Sorry, I failed to mention what bands I'm looking for...

I'm looking to cover 10 thru 20 meters and possibly 40. I'd mainly be interested in a antenna that would cover all 5 bands thru 20 (i.e 10, 12, 15, 17 and 20) or a tribander (10, 15 and 20) I think probably my best bet would be to have a antenna such as ones described above and then just use a dipole for 40 meters. I have no desire to get on 75/80.

Thanks
Matt

It's an interestin article. The usual configuration seems to be an inverted V/maypole setup, with 4 legs of unequal length. Good description of balun construction. Neat 4:1 current balun design using ferrite beads and RG-62 coax.

Construction is somewhat complex and the measurements may be a bit fussy. But it claims very low SWR on 80-10 including the WARC bands.

One wonders why it has not caught on here as in DL. I'd put one up but I don't have room for the four wires.

It would be an interesting antenna to model.

>The antenna I used matched
>the description above in this thread.

I don't know about that, but it's of little consequence. The single OCF dipole was in the Handbook for many years. As Dr. Belrose points out, it's NOT a Windom - it's an OCF dipole.
>
>> > It worked well on all HF

>You're right. I was only thinking about the WARC bands.

The antennas in the QST article do 80 thru 10 including the WARC bands.

Yes, you did, Tom.

I said: The basic question is whether common mode conditions are related to
differential conditions (or not).

> You responded: Then the answer is no, they are not related.

That's an absolute statement, Tom, and leaves no room for doubt. You
said common mode conditions are not related to differential mode
conditions implying not in any way whatsoever. Would you like to admit
that your statement was false and change it to be true?

> What I have said, time and time again, is common mode impedance (or
> voltage, or current) and operation is not related to differential mode
> impedance or operation, and it is a MISTAKE to assume they are
> directly related.

What you said was that common mode conditions are not related to
differential mode conditions. See above.

> In trying to get that into one sentence, the best I can come up with
> is to say "common mode impedance is not related to differential mode
> impedance".

But that's not what you said above. You said common mode conditions are
not related to differential mode conditions. I have offered any number
of examples where common mode conditions *are* related to differential
mode conditions.

Your statement above was and is simply false. It will remain false
no matter how many true statements you make. Why are you unwilling
to hold yourself to the same technical standards that you demand
of others?

I have no doubt that if the DOD had $1,000,000 for the project, they
could document and report the relationship of common mode conditions
to differential mode conditions in a test antenna system to whatever
accuracy is required.

"CAM"
> But theoretically, it will never reach exactly 1:1.

I once saw a spec for some lossy 'fibre optic' fibre - the loss was specified as being around "3400 dB per km" (IIRC). I wondered how the heck they would measure that much loss. Funnel a Universe full of photons in at one end and none would come out the other end. Eventually one photon might come out, but the Universe would be long since dead before that would be even remotely likely to happen. Obviously, to come up with that specified loss specification "per km", that they used a much shorter length (like 1m=3.4dB) and extrapolated.

Using such a lossy cable, and *taking into account the quantum nature of radiation*, the SWR would, in fact, theoretically reach exactly 1:1. You just need to use sufficiently lossy cable and the slightly more complete theory that includes the quantum nature of any radiation (including RF).

;-)

Why don't you go ahead and say whatever it is that you want to say? I
wouldn't feed a 300 ohm folded dipole with coax in the first place. (I
might use it for a matching section) Would you? You seem to be equating
that with matching feedline impedances, so explain yourself. Are you
saying that a 50 ohm line can't match any higher impedance? I've never
seen anything like that in print.
So how, then, is a transmission line different from an antenna, which
is in itself just a transmission line?

From ARRL Antenna book, 15th edition, page 26-12:

"Rearranging the equation gives Zo=(sqrt)Zi*ZL. (Zi=input impedance,
ZL=load impedance). This means that any value of load impedance Zl can
be transformed into any desired value of impedance Zi at the input
terminals of a 1/2 wv. line, provided the line can be constructed to
have a characteristic impedance Zo equal to the square root of the
product of the other two impedances. The factor that limits the range of
impedances that can be matched by this method is the range of values for
Zo that is physically realizable. The latter range is approximately 52
to 600 ohms. Practically any type of line can be used for the matching
section, including both air-insulated and solid-dielectric lines".

What say you?

Dick

Lossy is right. Even a 1 mm length would have a loss of around 3335 dB.
That isn't a fiber, that is a solid plug of dense matter.

What is 2^1133rd power? Divide 1 km by that and you will have the
approximate length that would provide a 3 dB loss.

Sounds like some sort of advertising hype to me.

I also have a 75 m loop up about 5-10 meters and with five corners. I am very happy with it - when 10 meters was at its best in March, I could work Brazil, Argentina, Japan at QRP - CW level from my location near Oslo, Norway. It does well on all other bands also, and I have worked JA on 40 m with it. However, it did require a modification to a standard Z-match to tune on 17 - 10 m, see more info at http://www.qsl.net/la3za/Homebrew.html.

Let's be honest Cecil. I was in a thread about a particular system,
and you still had a chicken bone stck in your craw about the balun and
the tuner.

The truth is, you get attention from these long useless arguments even
if no one on the newsgroup learns a thing because of them.

That is what is important.

Source record: 139287

One interesting thing I've noted about the 80m loop, it's the only one that has a feedpoint impedance of between 200 and 300 ohms on all bands 80-10m including warc. Other loops including 160m and 40m sizes will present some very high and reactive impedances on some bands. This makes the 80m loop somewhat special since it is the easiest to feed and tune. This is the only loop that one can feed directly with coax without a huge amount of power loss on some bands.

The ideal system would use 300 ohm feed line and a balanced tuner at the transmitter. A 4:1 or 6:1 balun will work nicely with the 80m loop. I've used a 4:1 W2DU current balun at the antenna's feedpoint with a 50 ohm coax feeder and found little or no matching is needed on many bands.

If your goal is making the 80m loop resonant on multiple bands, be sure to do the math. If you cut the loop for the ssb portion of 75 meters, it will not be resonant on the higher bands. Cut and tune the loop for the low end of 80m and you should find the harmonics fall within the ham bands.

As for your 20ft height question.....I've never used one that low. My loop is at 50ft. The problem with such a low loop would be signal absorbsion from surrounding objects such as your house, the earth etc. Feed Z on 80m would be considerably lower than the other bands. -- 73 --

First let me start out with a big THANK YOU to those who replied. It appears the 80m loop does have some benifits in loading. Not much feedback on lobe patterns but I assume the DEMO EZNEC did validate what was suspected is that 80m was a cloud warmer (good for local contacts, 40m was sort of a mix with some high angle and some lower angle in the range of 35 degrees or so. On 20m and up and above you get some gain (3db or so). But more importantly on 20m+ you get primarily low angle lobes (25 degreess and a bit lower) without a lot of high angle lobe patterns (placing your power where you want it).

The difference between 20ft vs 40ft appears to be not so much a matching factor but more importantly what lobe patterns do you want to achieve.

This may be why CEBIK chose 35ft for his horizonal loop (besides being an achievable loop height).

Appears what we need is a set of 4 tall masts (40ft or so) and raise and lower the loop for varying band conditions and station location (both yours and his) to get the best signal (smile)

The important thing from all this appears to be that a loop is a good COMPROMISE all band antenna (80-10m), with very few negative aspects and relatively good performance if you choose the right height for your type of operation.Fairly quiet, some modest gain on upper bands and probably quite comparable to dipoles at the same height. Is this a good summary?

Whether you would or would not feed a 300 ohm folded dipole with coax is
irrelevant. Please describe how to use a single piece of lossless 50 ohm
coax as a series section transformer to transform 300 ohms to 50 ohms.

> Are you
> saying that a 50 ohm line can't match any higher impedance? I've never
> seen anything like that in print.

Yes, I am saying that a 50 ohm lossless series section of line cannot be
used to match any impedance higher (or lower) than 50+j0 ohms to exactly
50+j0 ohms. The only load that Z0 transmission line can match to Z0 ohms
is Z0 ohms.

> From ARRL Antenna book, 15th edition, page 26-12:
>
> "Rearranging the equation gives Zo=(sqrt)Zi*ZL. (Zi=input impedance,
> ZL=load impedance). This means that any value of load impedance Zl can
> be transformed into any desired value of impedance Zi at the input

> terminals of a 1/2 wv.

The equation proves what I have been saying. If you can use a piece of 50 ohm coax to transform a load of 300 ohms to 50 ohms, then you can prove that 50 = 122.5. Do you really think that 50 = 122.5?

When varying the length of the transmission line to achieve a match to 50 ohms, a Z0 of 50 ohms will fail to achieve a match to any load except 50 ohms. Varying the length of my ladder-line to match my non-resonant loads to 50 ohms only works because the Z0 of the ladder-line is not equal to 50 ohms. I am deliberately causing an SWR of around 9:1 so that Z0=450 divided by 9 equals 50 ohms.

Let's be honest, Tom. Why are you unwilling to hold yourself to the
same standards that you demand for everyone else? Do you have a
chicken bone stuck in your craw?

Also, after being transformed by ladder-line to who-knows-what
impedance probably not even close to the known antenna feedpoint
impedances, a 4:1 balun would be a bad choice.

Thanks Jim,

However, after taking a closer look I see it is rather dinky. Probably
best for lower power applications.

I tried a search for the specs but came up empty handed.

Thanks again

It's funny that Cohen's challenge to a debate went quiet after
this post.

519. Another 'Back To Basics' - Cable loss (in dB !!!) is proportional to length

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-07 14:50:43 UTC
From: " J. Harvey" <JM002.Harvey_TRIMTHIS_@Sympatico.ca>
Message-ID: <UyYV8.184$c_2.62662@news20.bellglobal.com>
Source record: 139262

J. Harvey mentioned:
> I once saw a spec for some lossy 'fibre optic' fibre -
> the loss was....around "3400 dB per km" (IIRC).
> ... [or about] (1m = 3.4dB) ...

"Bill Nelson" responded:
> Lossy is right. Even a 1 mm length would have a
> loss of around 3335 dB. That isn't a fiber, that
> is a solid plug of dense matter.
> What is 2^1133rd power? Divide 1 km by that
> and you will have the approximate length that
> would provide a 3 dB loss.

I've been confused by this topic (cable loss versus length) once before, but I thought that I had it figured out. The purpose of this posting is simply to make sure that I (or anyone else...) am not confused. Here we go - responses welcome !!!

It is a mental trap to start adding or subtracting 3.01dB while doubling or halving the length of the cable. It is a mental trap to start adding or subtracting 10dB while making the length of the cable ten times longer or ten times shorter. These mental short cuts are wrong. I've fallen into them.

Cable loss (in dB !!!) is *simply* proportional to length. If you double the cable length, then the number of dBs of loss is simply doubled (NOT increased by 3.01dB - unless by coincidence). If the cable is made ten times longer, then the loss (in dBs) is simply multiplied by ten (NOT increased by 10dB - unless by coincidence). If the cable is made one thousand time longer, then the cable loss in dBs is simply multiplied by 1000.

So, for the example given at top, the loss versus length table looks like this:

Lossy 'Fibre Optic' Fibre
==========
1000m or 1km = 3400dB (obviously an extrapolation)
100m = 340dB
10m = 34dB
1m or 100cm or 1000mm = 3.4dB (probably 'as measured')
(or about 1dB per foot)
10cm or 100mm = 0.34dB
1cm or 10 mm = 0.034dB
1mm = 0.0034dB

So, the statement that "...a 1 mm length would have a loss of around 3335 dB..." is not correct (right?). A 1mm length would have a 'quite manageable' loss of about 0.0034dB as per the table above (right?).

The length required to have a 3dB loss is simply a bit less than 1m (since 1m is 3.4dB), not "1km divided by 2^1133" (= 8.57 x 10^-339 m, there's not even a word for that number or length). Right ?

Responses welcome !

Yes, I do. The chiken bone is this.

I just asked you, in plain English, how you would suggest conveying to others the differential mode impedance of a system is not related to the common mode impedance.

Your answer, instead of saying anything constructive or offering a suggestion, was to return again to your silly word games.

I ask for suggestions on how you or others would respond to help people not fall into the trap of thinking common mode impedance relates to differential mode impedance, and you revert to the same old nonsense pulling things I said out of context just to continue your attention getting argument.

Either you have a better way to say it, or you have no suggestions. I assume it is the latter.

Message-ID: <ag9l4goqt1@paris.btinternet.com>
Source record: 139263

I am just completing a program to design coaxial antenna traps. The advantage over ordinary coil and capacitor traps is that a separate high voltage, high current tuning capacitor is not needed.

It occurred to me it may be possible to make a higher Q trap, easier to construct, with twin 150-ohm line or two parallel teflon-insulated wires forming one line.

Has anyone ever made or experimented with such a device ?

So far you're the only "authority" I've seen in 45 years of reading
that insists that you have to have a high SWR to match an antenna.
Maybe that's required, but it sure is curious that it doesn't appear
anywhere in the literature. It sure seems it would, if so.

In the latest issue of the ARRL Antenna book, are several designs similar to the ones you describe. One of these uses two parallel Rg58 coax coils. Properly designed, these easily handle the legal limit and then some.

As for the Teflon ones, why not?

> I think it is a very important report either way. If there is such a
> fundamental discrepancy in 1997, that is big news. If the report is wrong,
> that is big news too.

Reading the infamous document again, I was struck by a few more thoughts.
The abstract sez that the report is to resolve 6-dB discrepancies that have been
noted between measurements and predictions of ground wave transmission. Their
predictions use a 5.17 dBi gain (2.17 dBi + 3 dB) for the transmitting monopole, a 5.17 dBi gain (2.17 dBi + 3 dB) for the receiving monopole, and an effective
area that has been "corrected" by the addition of a 1/4 fudge factor (wait a
minute, that's -6 dB!).

Rather than adding a fudge factor, could the problem just possibly be the 5.17
dBi value? This value comes about since the gain is evaluated only over the
upper hemisphere above the infinite ground plane on which the monopole is
located. The power is radiated into half the volume for which the dipole
radiates its power. But does a 5.17 dBi gain value actually make sense? Is the
monopole EIRP twice that for a dipole for identical input power?

A 2.17 dBi gain for both the transmitting and receiving monopoles would resolve
any discrepancy without the need to resort to a fudge factor. I can see that
the infinite ground plane adds 3 dB to the gain. However, I also seem to recall
from some long-forgotten tome that there is another factor that *subtracts* 3 dB
to bring the gain back to 2.17 dBi. The monopole on a ground plane would
then be identical to a dipole in free space. I guess that's what would be
expected. Maybe when I get back to work I can look through some of the old texts

there.

I'm hoping that some of the regulars here will dig in
> to the report and come to a consensus.

Not until the discussion as to "not" and "related" plays out.

John is correct! A groundplane for a vertical is not one or two wires cut for each band, but rather a 100 to 120. This is something the manufacturers don't tell you. Oh yes, they work even with a ground rod, but the losses are VERY great.

I'm not an expert, but I have experience with this set-up because that is what is used in my local. I live in the Mohave Desert, and my property is about 5 miles from the power distribution sub-station. From there it runs to my property via a buried high voltage line, and then into a buried step-down transformer which is about 100 feet from my house.

In my case, I have no noise level problems. Above 75 meters I have a "0" noise level 99% of the time. At 75 meters and below, it can vary occasionally from 1-2 "S" units up to about S-5 on 160 on a "bad" day. But this is mostly from atmospheric noise, it does not seem to be an electrical power related interference.

Compared to my last QTH which was in the city - with power lines on poles - I typically had S-5 to S-9 noise on any band most of the time. Personally, I'll take the buried power lines any day... :>)

Hi Jeff,

This is an exceedingly abysmal grade of cable (a string of
superlatives couldn't adequately cover it) unless it is a special
purpose, short haul variety. It appears the original poster
pencil-whipped it (as revealed through your table) when he trimmed it
back to 1mm.

Tom, W8JI wrote:
"I just asked you, in plain English, how you would suggest conveying to others the differential impedance of a system is not related to the common mode impedance."

Don`t make that flat statement as it is blatantly wrong.

Richard Clark suggested using a resistance bridge example to explain the relationship between differential-mode and common-mode. Let`s try it.

Call the differential-mode the bridge excitation. Call the common-mode the signal driving the null detector. The roles are reversible. We are just picking the familiar.

When the bridge is balanced, the
differential-mode produces zero common-mode null detector signal.

There is certainly a relationship between the excitation and null reading whenever the bridge is unbalanced.

There is also a relationship between impedances in the bridge and that of the null detector. (maximum power transfer has not been repealed)

The same is true for the differential-mode/common=mode systems we`ve discussed. Tom has consistently taken the wrong side of the argument and now posts diversions.

It is interesting how a simple 1km long roll of lossy, short haul, 'fibre optic' fibre, that might easily fit into the trunk of you car, can so completely defy the capabilities of a normal calculator that 'only' goes up to 9.999...x10^99.

Source record: 139176

Thanks for the interesting discussion. There are several variables
that
may need addressing. Normally a 1:1 transition balun is sufficient for
using an 80 meter horizontal loop in the multiband operations. But
depending on the length of feedline, and sometimes there is not a
choice as to the "best" length, then having a 4:1 balun is so very
valuable to be able to switch over and use also with the 1:1 balun.

Personally I use 160, 80 and 40 meter horizontal loops which all
are between 10 ft to 20 ft above ground and a selectable balun
box with 1:1 and 4:1 baluns available and all the horiz. loops are
fed with 450 ohm ladderline or 300 ohm twinlead. The 3 loops
are fed with seperate feeders and the unused ones are grounded
at the shack. These loops are nested inside each other and being
as close to center of each other as possible. Point being is that
no single antenna can do it all, but with the three-some there is a
flexibility that was worth all the effort of putting up the hz loops.

At FD this year, we used a 40 meter loop up at approx. 15 ft and
running QRP SSB (5 watts PEP), it was not an unpleasant chore
to work 40, 20 or 15 meters SSB. This was the first time ever that
I tried the QRP SSB on FD and it really works. Yeah, I was so
surprised.

Happy hz loop buiding...73...Walter, AG5P

Anybody can go straight to Terman and read the right values for the gain of a dipole over an isotropic and the gain of an antenna restricted to a hemisphere over that allowed a whole sphere. He can also read that the qiuarter-wave rod mounted on a large conductive sheet has zero dbd gain.

Terman`s publications have withstood 70 years of challenges. Challengers need more than a casual report to merit attention.

Best regards, Richard Harrison, KB5WZI

536. New program COAXTRAP

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-07 17:39:10 UTC
From: Reg Edwards <g4fgq.regp@btinternet.com>
Message-ID: <ag9ubtqvi1@helle.btinternet.com>
Source record: 139178

New program COAXTRAP.exe

Coaxial traps are often inserted in HF dipole antennas to isolate the ends of the wires from the the feedpoint thus shortening the effective overall length of the antenna. The antenna is then resonant in a higher frequency band. A trap is a parallel tuned circuit which is adjusted to resonate at the higher frequency.

A trap is constructed from a length of coaxial line wound as a solenoid on a cylindrical former. The program models the construction operation by assisting the designer to wind on turns until the required resonant frequency is achieved. The normal coaxial capacitance behaves as the high-voltage tuning capacitance although there is a transformer action in the manner of connecting the ends of the line together. This small program will be interesting even if the user does not intend to make any traps.

This program has been tested by me on only two actual traps - one using 75-ohm coax and the other 50-ohm RG 58 on different diameter formers and different numbers of turns. Errors in predicting resonant frequency were less than 1 percent but great care was taken with measuring and checking dimensions. It would be appreciated if any constructors who have a trap in the shack doing nothing could measure it up and check frequency. If anything is suspicious please let me have the data and how it was obtained. It is possible on my solitary pair of samples I could have made a common error. The best way to measure resonant frequency is to use an antenna analyser on the Z range. Use a thin single-turn coupling loop around the middle and 6 or 10 inches of loosely-twisted pair to the meter. Look for a very sharp peak in Z.

Download COAXTRAP in a few seconds from website below. About 31 kilobytes. Not zipped up. Run immediately.

> to the report and come to a consensus.

I'm not a regular poster -- mainly just a lurker -- but here goes:

Let's keep track both of power used and of field strength in the following two thought experiments.

(1) Consider a ground plane and two monopoles, opposite each other but separated by the ground plane. Feed each one with one watt apiece, 180 degrees out of phase. See what the field strength is at arbitrary points on both sides of the ground plane.

(2) Remove the ground plane and the two monopoles, and install a dipole where the two monopoles were. Feed it with two watts. See what the field strength is at arbitrary points on both sides of the former location of the ground plane.

Perhaps this may shed some light on the situation.

538. 1000 fraudtenna_dollar COMMON MODE CHALLENGE

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-07 18:19:16 UTC
From: Richard Clark <kb7qhc@attbi.com>
Message-ID: <1hsgiu0femmpeksto5bbtj3j3vdsbcsa53@4ax.com>
Source record: 139180

Hi All,

Today's CHALLENGE is to find the Common of the Common Mode.

>Here is the context, published by myself many days ago.
>XMTR---x---coax-----choke---1/2WL ladder-line---well balanced 1/2WL dipole
>
>Common mode measured at 'x'.

Myself, having been pleaded with to subscribe to a theory based upon the argument provided above, I asked where the Common was given the theory made an appeal to it. This has proven to be one of the most elusive goals for many here since Kirchhoff settled it two centuries ago.

That first question, again, was:
What is the Common of the Common Mode?
In a technical group, I would have presumed that Common had an ordinary meaning of the path where the current returns to its source. It is frequently ground, an all encompassing concept that in circuitry is often the negative lead, or the chassis. But not always.

I then, with hesitation, tried another approach:

The thesis is that XMTR is the source of Common Mode current, my second question is:
Where is the current flowing toward at any point in its cycle (choose your own point except at the zero crossing of course)?

Third question:
Taking that same point in its cycle, can you describe the complete path of current flow?

Fourth question (#2 & #3 combined in a manner of speaking):
Once the Common Mode current (at that same point in its cycle) reaches either the XMTR or dipole, how does it return to its source?

Kirchhoff teaches that if a current exists, it must return to its source in a loop (by passing through what is the Common). If we simply discard the term Common or Common Mode, it is obvious that the current still has to be supported by a loop topology and the questions above are still meaningful (they don't require any notion of the differential or the common). In this sense, the questions are answerable and indeed offer the same answer regardless of the terminology. It is equally obvious that the circuit described above by quote is a linear path and does not conform to a loop to support

current unless this context is incomplete (a frequent problem).

As a gesture to eliminate the inordinate baroque features of the original problem, I offered that this is all resolvable through a simple bridge topology. How so? someone (might have but did not) ask.

The Differential Mode is simply the Common Mode with a 90ï¿½ turn with respect to ground such that the loop (nothing happens in electronics without Kirchhoff's loops) potentials maybe balanced with respect to earth. Balance is not necessary, but it does serve in the reduction of variables as the two modes come with their unique problems (the reason why debates rage on so). In other words, the Common Mode maybe (from its perspective) in a Differential Mode to the original Differential Mode circuit under scrutiny. This is the point of the first question:
Where is the Common of the Common Mode?
in that by turning the perspective (reference) 90ï¿½ you can invert the semantic relationship without having done anything to the entire circuit under consideration. Given that debates rage over semantics to the exclusion of technical discussion, the question, even though simple, confounded most.

For the matter of potentials it is as elementary as asking, where did you put your reference lead when you make a voltage measurement? For the matter of currents, it is as elementary as asking where is the current sink? Measurements without a point of reference are meaningless. If we speak of potentials and measure from one point to another and say we have found a Differential Mode voltage, it follows that both leads were isolated from ground (the common understanding when unstated otherwise). If we speak of potentials and measure from one point to another and say we have found a Common Mode voltage, it follows that at least one of the leads was attached to ground (the common understanding when unstated otherwise).

If I can satisfy the above considerations, and then state that in fact the Differential Mode potential had ground as a reference, there is no problem as long as we don't make the same claim for the Common Mode potential by saying one lead went to ground. [this is the real problem where grounds/commons become mixed] We have simply changed our perspective and chose to name the circuit with the ground reference Differential Mode (there is nothing to preclude this except the eventual confusion of conventional usage of these terms). By extension, the Common Mode must become a floating circuit with respect to ground and the Common of the Common Mode is found in one of the floating leads. Hence, one can easily describe a current measurement as being Common Mode in stark contrast to common usage without being wrong - unless, of course, the measurer does not or cannot describe the reference, the Common of their Common Mode.

If you cannot describe the Common of Common Mode, it is likely because you do not have a complete picture of the entire circuit. Making appeals and generalizations to having shown its effect without being

able to describe the circuit is at best one of luck and offering it as a "proof" is no proof at all.

By taking the conventional meaning of Common to be ground, the CHALLENGE is thus:
Offer the "complete" context to the implicit problem quoted above in the form of a circuit diagram. My preference is that you reduce it to four resistors, source and detectors (with suitable annotation to correlate to the original) - but this is not necessary.
It goes without saying that the winning description must satisfy Kirchhoff's laws (fractal Electro-Hydrodynamics disqualifies you immediately).

ALL winners of the CHALLENGE will be immediately e-mailed 1000 fraudtenna_dollars in virtual currency - you can spend it virtually anywhere! [please note that limitations imposed by various states differ in the regard of unregistered lotteries: offer void where permitted by law]

Without 50 lines of rambling jargon, please tell me how to convey in
simple terms that the common mode impedance or actions of a system are
not tied to the differential mode impedance or operation of a system,
and that picking a low impedance point for a choke balun does not help
the system balance or improve action of the balun.

For example, in the case of the EH antenna adding a W2DU balun at at
low impedance differential mode point might not change the operation
at all, and if it does it might make it go any direction at all.

As another example, altering a feedline to acheive a low differential
mode impedance might make balance problems worse, better, or not
change them at all.

As another example, adding a balun at a certain differential mode
impedance or voltage point can make a feedline system radiate more,
less, or not change it at all

Any single sentence you like, and let's see how it comes out. Surely
you can get it into one simple sentence, like "Common mode behavior is
unrelated to differetial mode behavor" or whatever you like.

But lets not dance around the whole universe to explain a simple
concept, like the relationship can be ANYTHING or nothing.

Hi Jeff,

That distraction is one like the morbid fascination of examining roadkill. Given the weight of math that comes with equal portions of obfuscation from some corners of science, could you pose the issue you perceive in terms of what you expect might be shown to fail in modeling compared to say the FCC field strengths for AM broadcast antennas (I offer this as a reference given how poor some may be at making measurements that only compound the error)?

I did note their issue, and their math, but I have had to instruct too many engineers and scientists (much less a parade of bozos, also spelled PHD, who held themselves in high esteem) that they were not equally talented in measurement.

Tom W8JI wrote:
> I just asked you, in plain English, how you would suggest conveying to
> others the differential mode impedance of a system is not related to
> the common mode impedance.

There you go mealy-mouthing again, Tom. You said common mode *conditions*
are not related to differential mode *conditions* and that was a false
statement. Are you willing to reverse your mistake and admit that it
is possible for common mode conditions to be related to differential mode
conditions or are you incapable of admitting a mistake?

Why do you hold other posters to a higher standard than you hold yourself?
It doesn't matter how many true statements you make if you are unwilling
to correct your false statements. You dish out a tremendous amount of grief
to others when they are mistaken but you seem to want some sort of guru waiver
against receiving any grief when you are mistaken.

And of course, the common mode impedance can be related to the differential
mode impedance. All we have to do is measure them to determine the relationship.
At least the conducted portion of common mode Vs differential mode obeys
Kirchhoff's laws. If we measure 10 ohms of common mode impedance and 50 ohms of
differential mode impedance at the antenna feedpoint, we are likely to want to
change that 10/50 relationship to a 1000/50 relationship by adding a choke. If,
as you say, there were no relationship, we couldn't change the relationship by
adding a choke, now could we?

"David Ryeburn"
> Perhaps this may shed some light on the situation.

I've been previously assured that it might shed RF on the situation, but not light. :-)

If you 'squeeze' the full two watts that you have on offer into the half of the universe 'above' the infinite ground plane, then it seems reasonable that the field strength everywhere (in the 'upper half' of the unverse) will be twice that which might be found with a dipole that must fill twice as much universe.

It seems like a mistake to lable this effect as an increase in the 'gain' of the monopole versus the dipole. How it would relate to receive mode gain is unclear to me.

Something 'stinks' in EM-land.

543. White City, OR Tower

Newsgroup: rec.radio.amateur.antenna

Those pictures of the tower and antennas are Cellular (PCS)
Probably Sprint.
They are sectorized. The T part on top is the antenna mount.
There are 3 sets of 2 antennas each pointing 120 degrees from
its neighbor. Usually it is at 0, 120, 240 azimuth.
If you have only one carrier... the second antenna in the pair
is for spacial diversity. It adds another 3 dB of gain by simply
being located a few wavelengths away from its buddy antenna.
After the cell site reaches it capacity another carrier is added and
is connected directly to the second antenna and there is no longer
spacial diversity on either carrier.
If a third carrier is added a whole new antenna array is added...
usually about 10 feet or so below the original.
There poster on the tower looks like a FCC/FAA antenna
registration sticker.

You can certainly match a 50 ohm antenna to 50 ohm coax with an SWR
of 1:1 so you misunderstood what I said. Here's a correction to what
you inferred that I had said: It is impossible to do any impedance
transformation on a single series section of transmission line unless
the SWR is higher than 1:1. SWR doesn't have to be "high", just higher
than 1:1. You can use 75 ohm coax to convert 112.5 ohms to 50 ohms
because the SWR is not 1:1. It is 1.5:1. 112.5/1.5 = 50*1.5 = 75
All series section transformers carry an SWR above 1:1.

Most of the authors probably assume that you can read a Smith Chart, Dick.
If you cannot, that's not their problem.

When you use 50 ohm coax with a Smith Chart, the normalized 1.0 + j0 point
in the center of the Smith Chart is the 50 + j0 point. Draw an SWR circle
on that Smith Chart. Does the circle intersect the 1.0 + j0 point? If
not, you cannot achieve a match to 50 + j0 ohms using just 50 ohm coax.

Hint: A circle does not intersect the point at the center of the circle.

The issue here is that 'Theory 1' (their formula as presented) doesn't agree with 'Theory 2' (Mini-NEC - supposed to be based on Maxwell's Equation ?).

Measurements shouldn't (yet!) have to enter into this debate (although the final selected Truth had darn well better agree with good measurements).

> the system balance or improve action of the balun.

Picking a low impedance point for a choke balun indeed does help
improve the system balance in my antenna system. I have already
posted the measured values. The common mode current is minimum
when I feed my antenna system at a current maximum point. That is
a fact. Please read Roy's article, "Baluns: What They Do And How They
Do It", and get back to us on the errors that you find in that article.

You have simply gone overboard in trying to defend a simple mistake.
Why not just admit you made a simple mistake and move on? The hole
that you are digging for yourself is getting deeper and deeper.

The mistake I made earlier was assuming that moving the choke moved
the unbalanced/balanced point in the system. It doesn't and I was
wrong about that. But if the unbalanced/balanced point is moved along
with the choke, the differential impedance is one of the factors
in the cause of common mode currents as can be seen from the following
example posted earlier.

#1XMTR---worst case length of 50 ohm coax---500 ohm choke---50 ohm antenna

#2XMTR---worst case length of 50 ohm coax---500 ohm choke---5000 ohm antenna

The choke in #1 will do a better job of controlling common mode currents
than the choke in #2. If common mode impedances are unrelated to differential
mode impedances, how do I know that? How can anyone be an expert on common
mode conditions if common mode conditions are unrelated to differential mode
conditions. Are you divinely inspired or what?

Your argument gets more divorced from reality all the time. The differential
current flowing into an antenna feedpoint can be measured. The common mode
current flowing down the outside of the coax at the antenna feedpoint can
be measured. Their relationship is their ratio. To maintain there is no
ratio, i.e. there is no relationship, is sheer insanity.

Hi Jeff,

Look at the introduction:
"... it is this value of effective area that resolves the 6-dB
discrepancy between measurements and analysis...."

Measurement appears to be quite centric to their problem. Again, it
goes to show that someone might measure anything and call it what they
will.

Without accepting outside sources or references, almost any statement
can be made and the debased imprimatur of Science applied to it.

Deja vu all over again. That`s wrong except for the trivial case when perfect balance exists.

For example, a coax-fed dipole puts r-f on the coax. Change the coax length and r-f on the coax changes. We did not change surge impedance of the coax, only its length. R-F on the coax indicated system imbalance and is a measure of common-mode current.

Measure differential-mode before and after the coax length change. It too changed because the antenna load changed as more or less energy was accepted by the coax exterior.

More clearly, don`t change the coax length. Just put a W2DU balun on the coax and move it around. All the above is still true.

Moving a balun along the coax would not affect the loading of a transmitter if common-mode were unrelated to the differential mode.

Antennas are completely reciprocal. They have the same characteristics receiving as transmitting. They do both at the same time because they don`t know which mode they are supposed to fill.

the buried hv line should be quieter overall than one on poles. insulators on poles are always subject to contamination and weather that can cause corona and arcing which generates noise. buried hv is immune to that. a ground mounted transformer is normally in a steel enclosure and burying the line to the house keeps that protected also. that kind of arrangement should also be less susceptible to lightning damage.

the only thing to be concerned about is if they want to charge you for the work, buried hv lines are generally much more expensive than poles

In my experience, you shouldn't have any problems with the buried line... just maybe the power transformer above ground... and usually not from a new one like that.

Just be sure you know mark where there line is underground so you can avoid problems when erecting your antenna farm.

PS: I'm curious how long that underground run is. If its not too long, couldn't they put the transformer on their pole and run 240/120V to your house underground?

I have the 18th edition of the antenna book. I searched it and found an entry only a small fraction of a column long about a trap wound with coax. There is a photograph which shows construction method but complete absence of dimensions and resonant frequency. This is surprising because I am under the impression such traps have around for many years. I can remember experimenting with one 15 years back. Or did I invent it ? ;o)

What is the latest Antenna Book issue number please? I would like to see the coax trap sections to obtain dimensions.

Agreed.

> How it would relate to receive mode gain is unclear to me.

If you run time backwards, what's the difference between transmission and
reception?

> Something 'stinks' in EM-land.

I doubt that. But blaming either the monopole or the dipole for the type
of universe (semiverse?) it is supposed to radiate into seems unfair.

the xmitter may be the source, but currents can flow over, under, around,
and through it on their many and varied paths. just ask anyone who has been
burned by rf on a chassis.

yep, once you get larger than that small fraction of a wavelength you have
to consider much more than just current going out here comes back there in a
simple loop. the simple dc analogies don't work in the case you describe as
there is no simple closed loop to account for all the current.

> first question:
> Where is the Common of the Common Mode?

common is measured at a point where two or more wires pass. you simply
measure the currents that are 'common' to all the wires. of course it is
not a simple job when there may be larger currents going different
directions in each wire. make it a 3 or 4 wire problem and you can generate
all sorts of different 'modes', ask a utility engineer about all the
possible modes of a 3 phase hv line over real ground... make it a double
circuit 3 phase line and have even more fun.

> in that by turning the perspective (reference) 90° you can invert the

> common understanding when unstated otherwise).

again, grounds are problematic in measuring rf where anything is larger than a small percentage of a wavelength. a 3' ground lead on 10m is 10% of a wavelength and introduces a phase difference between what it is hooked to as a ground and the meter. use it on 2m and you are 180 degrees out of phase.

>
> If I can satisfy the above considerations, and then state that in fact

again, grounds are problematic. any wire could be designated 'common' or 'ground' but it may have a current or voltage on it relative to any other object, or even itself a short distance away.

> our perspective and chose to name the circuit with the ground
> reference Differential Mode (there is nothing to preclude this except

> as being Common Mode in stark contrast to common usage without being
> wrong - unless, of course, the measurer does not or cannot describe
> the reference, the Common of their Common Mode.

ah, but that is the key. the person making the measurement is free to define any point they want as the 'reference' as long as they are consistent and take into account distance and time to arrive at consistent loop currents and node voltages they are right. for convenience the source chassis is often used, but it doesn't have to be. if it is more convenient to measure with respect to some other point you are free to do that.

>

kirchoff's laws as usually stated in undergraduate circuit theory just don't hack it here... unless you go to great pains to replace each piece of the problem with a lumped equivalent circuit.. .and then analyze the many, many, possible current loops.

I asked a simple question, and you try to go back to your system.

In many or most systems, what you claim is NOT true. The reason it is not true is common mode impedance and distribution of that impedance has nothing to do with the differental mode impedance and distribution of that impedance of a system.

The impedance, losses, and velocity factor of the two modes are distinctly different in the vast majority of systems.

For example, the velocity factor of a RG-8U cable in differential mode is about .66, yet in common mode...hanging in air...it is almost unity.

This (another new example) often confuses people who think throwing a few beads here or there on a cable reduces common mode current, or people who design sleeve baluns or other systems dependent on the velocity factors both inside and outside the cable.

If we misterminate the cable both for common mode and differential mode to create standing waves, the standing waves of one mode have nothing to do with the other. They each independently establish their own current maxima's and voltage maximas, and they even don't occur the same distance apart. As a matter of fact, one can be perfectly terminated and the other grossly mismatched.

With that in mind, how do we explain that effect (in a manner that you will permit) to people trying to understand systems?

Not your particular system, but the dozens or hundreds of other systems.

Thanks,

Tom W8JI

>adding a choke, now could we?

That is where you make another serious mistake, unless you carefully
define the system.

The common mode impedance is driven by a voltage or source someplace,
and the reduction of power from that source only has to do with the
change in common mode impedance when we add the balun. For example, we
can have an across impedance of 50 ohms but a source voltage driving
the common mode system of several hundred volts even at low power.

An example of that is a vertical, like the small ground independent
verticals.

They have a differential impedance of nearly 50 ohms, but many
hundreds of volts driving the common mode system.

With that in mind, how do we explain that obvious disagreement with
your view based on your antenna system, or in a specific system that
might be used as an example in a balun article about a particular
system, when many systems do not follow those same rules?

I would like to do an end fed 6m wire. I have a strict antenna policy with the wife.NONE outside.We don't need to get into that part though.1)I just wondered how long it would need to be 2)do I need a balun?3)which direction would be best to run it for my central Ohio location?
It will be in the attic and I will use it primarily for SSB
I currently have a G5RV Jr. and a 2M 4 element Cushcraft beam on an inop rotator in the attic
These all are used on my Icom 706 and Yaesu FT-1500
Oh yea my approx. height to the antennas is about 12ft.
Thanks Gents and Ladies!

Cross-posted to: rec.radio.swap,rec.radio.amateur.homebrew,rec.radio.amateur.antenna

I have just acquired over 700 pounds of bare #9 solid copper wire. I'm going to use some of it to redo my radial system, but the rest is for sale.

The lot includes lengths varying from about 33 feet to 37 feet. (Splice it together with pieces of 1/8" copper tubing to make longer lengths).

Asking $1.75 per length. (Less than 6 cents per foot!) 6 lengths for $10.

Pickup in Yorktown Heights or White Plains NY area. Will consider delivering nearby if you want the whole lot. Will also consider shipping if quantity is both worthwhile and manageable. (A 37 foot length weighs about 24 ounces. Buyer to pay shipping).

> will permit) to people trying to understand systems?

The analogy you introduced concerning solar systems is a good analogy. There is no way to predict the composition and relationships of a solar system that we have never seen. But once we see it, we can ascertain the composition and measure the relationships. There are some laws of physics that all solar systems obey but much about any specific solar system is unpredictable before it is discovered and explored.

There is no way to predict the relationships in an antenna that we have never seen. But I am sure you can look at a lot of antenna systems and predict that they are likely to have common mode problems and on top of that, what steps to take to minimize the common mode problems. Your previous example of a dipole feedline coming off at a 45 degree angle under one side is a good example.

> Not your particular system, but the dozens or hundreds of other
> systems.

The relationship between common mode conditions and differential mode conditions are partially predictable and partially unpredictable. Just because a relationship is unpredictable doesn't mean it doesn't exist. It is OK to say we don't know the exact relationship but it is foolish to say that two signals of the same frequency from the same power source are unrelated.

You make the same point if you say common mode conditions and differential mode conditions during transmit are often related in an unpredictable manner. But we can probably make some valid predictions about conducted common mode currents as Roy did in his Balun article. For instance, if we change a well-balanced dipole to an off-center-fed configuration, we will probably increase the magnitude of the common mode current at the antenna feedpoint. When I did that, the measured common mode current increased by a magnitude.

I am not defining the system, Tom. The system exists in reality. I am merely making measurements to discover the various relationships. If I don't have any common mode problems, I probably won't make any measurements and will remain ignorant of the various relationships. But my ignorance doesn't dictate reality and render those relationships unrelated. You seem to think that ignorance has some supernatural effect on reality.

> With that in mind, how do we explain that obvious disagreement with
> your view based on your antenna system, or in a specific system that
> might be used as an example in a balun article about a particular

Most antenna systems are measurable. If an antenna tuner knob setscrew burns a hole in one's finger, one has made a crude measurement. More measurements may have to be made to find out the best placement for a choke but we can probably say there exists a solution. Think about the mental steps that you would go through to try to solve a common mode problem. You are following a general set of *rules*. If common mode conditions were truly unrelated to differential mode conditions there would be rules to follow and common mode problems would be completely outside of our control.

Andy,
Actually, no, he wasn't, and still isn't. A tuner doesn't
adjust resonance, it matches impedances. Completely different
thing. The 'antenna' is still nonresonant, which doesn't mean
it won't work.

"David Ryeburn"
> If you run time backwards, what's the difference
> between transmission and reception?

Is there a 'reactive field' surrounding a receive antenna ? We've just had a discussion on the relative phase of the E and H fields near a transmitting antenna. It was generally agreed that there existed a reactive field close to the transmitting antenna where the E and H fields were not "related" by 377 + zero*j ohms.

What about the 'near field' ? If an antenna were transmitting, the 'wavefront' would be very much non-planer. If the antenna were receiving, then the 'wavefront' would be much closer to planer (assuming that the signal source was far away). Even given identical signal strengths (very weak transmitting), the difference would be obvious to a skilled observer.

What about the fact that a transmitting antenna might radiate 'from the middle' with passive elements equidistant experiencing the same phase, whereas a receive antenna will experience the waves passing from front to back and those passive elements might be out of phase ?

If you were to run a film of a transmitting antenna backwards (time reversal), people would rightfully ask why all the RF in the neighbourhood was converging on the antenna like that. I can't imagine flashlights sucking light, let alone recharging their batteries, even if time runs backwards. [The only reason that the Universe doesn't run backwards is because of the warning written on the side of non-rechargeable batteries !] Tea cups break, but they don't spontaneously reassemble.

Three laws of thermodynamics (as slightly extended by Yours Truly):
1) You can't win.
2) You can't break even.
3) You can't quit.
4) You can't run time backwards.

Does anyone have a simple proof (or even an indication) that antennas must be reciprocal ?

Has anyone ever made an antenna that wasn't ?

Are all of the quantifiable characteristics the exactly same ? Even given that the fields in the vicinity are different (reactive versus 377+0*j ohms, and planer versus non-planer) ?

You can bring the system into resonance by adding a shorted stub
of the proper length to the center feedpoint. Once resonance
is reached, you can pump RF into the bottom of the stub
from a source that is low enough impedance to mimic the
previous short. :-)

"Richard Clark"
> Look at the introduction:
> "... it is this value of effective area that resolves the 6-dB
> discrepancy between measurements and analysis...."

Interesting, you're right (I'd forgotten that). The introduction does mention measurement. Measurements are not mentioned anywhere else in the report. The report is very much theory versus NEC. One can only assume that they have compared Mini-NEC against all the other NECs.

The report compares Kraus and "Eq. 18" against Mini-NEC. There isn't a problem with the Kraus's gain (so they say), only the end-to-end pathloss.

Something stinks.

If the basic theory is wrong, then that's big news.

If NEC is wrong on monopoles, then that's big news.

If the author(s) of NEC are wrong on basic theory, then that's big news (but not quite so big).

Hi Jeff,

Once again, you have to separate the effects from the characteristics that cause the effects. The near field's characteristics of impedance and geometry with respect to its surroundings are analogs of a lens in that the presence of this discontinuity in space distorts it to same purpose: reciprocity.

Example of reciprocity is most striking in the yagi. If reciprocity failed, it would be most apparent for this particular design.

If you can stretch your imagination (speaking to others than Jeff now, as his is most malleable), search Scientific American's archives about passive sonar (sometime in the past two years). They in fact rebuild the source of a radiation (at sound levels) observed through the detection of a random field of detectors replaying their detected same sound, in time synchrony - backwards. That is, each detector has its own re-radiator that when properly sequenced and playing the sound in reverse, all such detectors/re-radiators add at the origin of the initial source reconstructed.

Antennas drive me crazy and like you say, no one antenna does it all. I have an 80m horizontal loop at 50ft and a 40m loop at 30ft. For some reason, the 40m loop usually does better on 20 through 10m.
Sometimes I have the feeling that the big loop's take off angle is too low and I either loose lots of RF to the ground and trees or else signals are arriving at higher angles than the big loop can hear.
It's hard for me to force myself to lower the loop when I can get it up so high! Do you think the 80m loop would perform better at low heights such as 20ft? I'm willing to give it a try.

If the original noise source at the origin was (for example) an exploding stick of dynamite near the ocean surface and it was weakly detected by an array of hydrophones scattered around at some significant distance, having those same hydrophones replay the same small signal that they so weakly detected will obviously not recreate the effect of a stick of dynamite back at the origin.

Even having those hydrophones pay the ultimate price and literally explode with the largest possible amplitude signal, those signals arriving back at the origin will add up in phase only in proportion to the number of hyrophones. Use a hundred exploding hydrophones and you'll be only 20dB above the sounds of a single distant exploding hydrophone. This would still be far less than a locally exploding stick of dynamite.

Things can add up in phase - that is true. This doesn't mean that time can run backwards.

Scientific American is just the sort of breathless rag to leap from one to the other. I dropped my subscription because they were getting so 'over the top'. One example is how Scientific American (and others) went crazy over the Eve Hypothesis.

> Is there a 'reactive field' surrounding a receive antenna ?

Yes, I would think there would be. At most (only when the receiving antenna is conjugately matched [heaven help us! -- don't want to start *that* thread up again]) 50% of the incoming energy will be deployed elsewhere (into whatever we have for a receiver) and at least 50% of the incoming energy will be re-radiated. The latter process will involve "reactive fields" as well as a radiation field.

> What about the 'near field' ? If an antenna were transmitting, the

I thought about the non-planarity after I posted. If there were *lots* of such receiving antennas, each doing their appropriate jobs, then I would think the nearly planar field would be reconstituted by their re-radiated fields. If there were *lots* of such transmitting antennas, appropriately located and fed with appropriate power and phase, a nearly planar field could be synthesized (at least locally). I don't know if this is a satisfactory answer or not.

> What about the fact that a transmitting antenna might radiate 'from the
> middle' with passive elements equidistant experiencing the same phase,
> whereas a receive antenna will experience the waves passing from front to
> back and those passive elements might be out of phase ?

What if there were more than one distant transmitting antenna, appropriately synchronized, so that the passive elements *did* receive in-phase signals? It isn't the receiving antenna's fault that the time reversal seems only be working in one spatial direction. Again I don't know if this is a satisfactory answer.

You're getting closer to convincing me. Maybe I should stick to
mathematics and not dabble in physics.

> Does anyone have a simple proof (or even an indication) that antennas must

I'd like to see it too.

> Has anyone ever made an antenna that wasn't ?

Again I'd want to hear about such an antenna too.

These two things I tried (perhaps unsuccessfully) to deal with. But
nevertheless I'm now not convinced what I first said made sense.

No, that is NOT wrong Richard. Think about it a bit before shooting
from the hip.

The differential surge impedance of a line is determined by inside
characteristics of the line.

The common mode surge impedance is determined by what is OUTSIDE the
line.

They are entirely different in virtually every case, as is the
velocity factor.

Second, the terminations are different for each mode in nearly every
case. The load placed across the line is not equal to the load from
the line to ground.

That means the impedance, or ratio of voltage to current, changes all
along the line at a different rate and even often a different
direction as we move along the line.

With that in mind, how on earth can you say this??

>perfect balance exists.

??
That's a very odd response when the rate and slope of the impedances,
voltages,and currents can be in any relationship along the line
depending on termination, the line, and what is around the line.

Richard Clark wrote:
"---the question is and remains, is the Common of your Common Mode artifact earth?"

J. Harvey, I think, in a much earlier posting to this thread, asked the situation for a free space site of transmitter, coax, and dipole. Let`s use that example even if J`s example was different.

At the junction of the coax with the dipole, current from the inside shield surface usually divides between the antenna element with which it is connected, and the outside surface of the shield with which it is also connected.

Return of the current from outside the shield and from the element of the antenna connected to the shield is via displacement current exchange with the element of the antenna connected with the center-conductor of the coax.

Thus, the voltage on the antenna element connected with the the center-conductor of the coax provides the voltage reference "common to all conductors of a group" (the coax outer shield surface and the antenna element joined to it being the group). The earth is not the arbitrary reference in this case.

Best regards, Richard Harrison, KB5WZI

J. Harvey wrote:
"Does anyone have a simple proof (or even an indication) that antennas must be reciprocal?"

Yes. 99 and 44/100ths% of the time or more.
Countless measurements and observations confirm reciprocity. Antenna characteristics have been determined by transmitting from many locations into the antenna, and by receiving at many locations from the same antenna. Patterns and gains are identical whichever method is used.

Far-field and near-field complications are unnecessary to consider in reciprocity. The antenna conductor has a current in it and a voltage across, no matter how it got there. It may have come out of a feedpoint or off the air. It causes radiation the same way, which means production of induction fields and all the rest, weak or strong, depending on the signal.

Best regards, Richard Harrison, KB5WZI

Tom, W8JI wrote:
"No, that is NOT wrong Richard. (the common mode impedance or actions of a system are not tied to to the differential mode impedance of a system---)"

Turn-off the source of energy shared by both modes and their response to that energy ends. That is a shared action and evidence of a relationship. They form a consumers union. They are both dependent on the same source. So, they are hardly independent. As energy is funneled through one mode to reach the other, it can`t be independent because one mode can be interrupted to discontinue the other. Some independence!

When there is imbalance in the system shared by the modes, a perturbation in either mode affects the other. They are coupled, ergo they are related.

What if the driving impedance of the transmitter is a lot different
than the impedance across the transmission line during receive, e.g.
the transmission line acting like a shorted stub during transmit
and like an open stub during receive?

I don't have to use the external tuner but I just bought an IC-756pro
with one built in so why not use it? The point is that I don't have
to use an external tuner because the internal tuner won't work into
SWRs higher than 3:1. I simply adjust the length of the ladder-line
until the internal tuner will handle the load.

The point is that, as long as nothing changes, they are in a particular relationship, not any random relationship. Seems to me you continue to make the mistake of assuming that if the relationship is unknown to you, then it can be anything. That's not true. The relationship is what it is. That you don't know what it is, is irrelevant to reality.

Remember the coin toss I did in which you didn't know the outcome? Based on your above logic, you would say the outcome is still in doubt because you don't know what the outcome was.

The relationships may be unknown and unpredictable but they are what they are and are measurable and knowable. You are not going to observe the common mode current randomly changing magnitude and phase X times per second during key down transmit.

> with them together in the

I have a "Hoffman Box" installed about 4 feet above ground on the side of
the tower. The conduit comes up into the box and is clamped in place. The
cables loop out the bottom on the other side and then go up the NE leg of
the tower. Well, actually the NE and SE. There are 8 cables going up
including the rotor cable to the remote coax switch for the wire antennas.

Well, the tower and antenna work is pretty much finished. Now it's going to be mainly maintenance, or an experiment here, or there. Unless we get one of those big ice storms with a lot of wind. It's gone through winds gusting up to 70 MPH and survived one winter and one lightening strike so far.

Never heard of such a thing. Might be worth a couple of tries on the bench with
the dipper.

I've been using coax-cable-and-PVC traps (40 meter/RG-58 versions) since the
mid 1980s in a variety of antennas. All are based on the article by N4UU in QST
for December 1983/1984 (I'm not exactly sure which year). That design connects
the center conductor of one end to the braid of the other end, and then uses
the free ends as the trap connections. The N4UU article gives charts of trap
dimensions for various bands, using either RG-174 or RG-58 coax. I have only
used RG-58.

One thing I learned early on about these traps is that they all need
adjustment. Variations in coax cable and PVC pipe characteristics are such that
assembly from formulas alone is inadequate.

From my own crude measurements and the work of others, the unloaded Q of RG-58
coax-cable traps made with optimum coils (square or a little shorter) is about
150. That's less than half the Q obtainable from lumped-constant traps of good
design and the same dimensions, and a coax trap's LC ratio is not readily
adjustable. Coax traps are also asymmetrical.

The main advantages of coax traps are their low cost, ruggedness and being
constructed from easily available materials. In a simple 2 band dipole design
with 2 traps, the total trap losses are probably less than 1 dB, which is
probably tolerable in exchange for the convenience and size reduction. The
losses in a multi-trap antenna can be much higher.

Source record: 139145

Steve,
If it were mine, I'd leave it at 50 feet! Leaving
the 'matching' part out of it, the biggest change you
would probably see by lowering the 80 meter loop would
be an increase in 'take-off' angle and general shape
of the radiation pattern. Even at 50 feet, the 'take-
off' angle isn't very low at all, so personally, I don't
think you would be gainning anything usable.
There's no particular 'good' reason to lower your 80
meter antenna. The lower height 'thing' isn't desirable
as such. The original question was if a loop at a low
height was 'worth' doing. If the original postor could
have gotten a loop up at 50 feet, I feel confident in
assuming that he would have done so. I would have!

Can you justify your opinion ?

Here's mine:
If the basic theory is wrong, then that's big news.
If NEC is wrong on monopoles, then that's big news.
If the author(s) of NEC are wrong on basic theory,
then that's big news (but not quite so big).

All you need to do is explain why the previously referenced report isn't big news. You might be correct, but I can't think of a 'non-big news' explanation.

Even if the Zo of the transmitter were zero, the E/I ratio would start-out as the cable Zo for a while (time 'related' to the length of the cable), and then revert back to the normal antenna SWR mess. The Zo of the transmitter never enters into it. (?)

You're certainly correct that the receiver might be different.

Not the 'antenna' reciprocity though.

CAM wrote:
"---transmission lines acting like a shorted stub during transmit and like an open stub during receive."

A receiver can extract maximum energy only when matched to an antenna. The antenna`s radiation resistance is the source resistance for volts "generated" in an antenna.

When an antenna is matched to a receiver, 50% of the energy in the antenna goes to the receiver. The other 50% is reradiated.

There are T/R switches, isolators, directional couplers, etc. As Cecil noted, receivers and transmitters can have vast differences in impedance, but inherently, antennas are reciorocal.

Best regards, Richard Harrison, KB5WZI

Ramo, Whinnery, and Van Duzer 'Fields and Waves in Commumication
Electronics' section 12.31.

and yes, in the second sentence it does assume there is a 'conjugate match'.

and yes, you can have antennas that aren't reciprocal. they one example
they give is when the transmission path includes something like the
ionosphere that does not have 'strictly bilateral properties'. one other
example i have heard of elsewhere that can make antennas non reciprocal is
the introduction of ferrites in microwave systems. (not the same as beads on
coax!)

in the proof by ramo, whinnery, and van duzer (and probably others) this
would violate the assumptions that the conjugate match exist and that all
other parts of the system remain the same when exchanging the tx and rx
antennas to prove reciprocity. obviously if you change the external systems
connected to the antennas they will not necessarily perform the same way.
```

Rick, K1BQT wrote:
"If you and I are riding the same train, Cecil, we are "related" in only the loosest way---."

But if you are coupled?

Whenever changing one mode changes the other mode, it is because the modes are coupled.

The coupling is measured by Ohm`s law. We take the voltage of one mode produced by current in the other mode and call the vottage to current ratio the mutual impedance. This is the quantification of the coupling.

Best regards, Richard Harrison, KB5WZI

With my high school ham rig, I threw the switch(s). Nowadays, there's
usually a T/R switch/relay built in. It just seems to me that the
driving impedance of the transmitter would have to equal the loading
impedance of the receiver for the antenna system to be truly reciprocal.
Just a random thought.

If there is an SWR on the line greater than 1:1, the steady-state E/I ratio
will be anything except Z0. A 1/2WL dipole with a 1/2WL shorted stub hanging
from the middle would be resonant on a certain frequency. Would that same 1/2WL
dipole with a 1/2WL open stub hanging from the middle be resonant on that same
frequency? If not, it leads me to believe that the driving impedance
on transmit and the loading impedance on receive need to be the same for
the antenna to have the same characteristics on transmit and receive.

There are three definitions of "related" in my dictionary, Rick. One has to
do with kinfolk. One has to do with audio tones. Those two definitions obviously
do not apply to RF common mode conditions versus differential mode conditions.
The third and last definition that does apply in this case is:

"related - connected by reason of an established or discoverable relation"

The established relationship between common mode conditions and differential
mode conditions during transmit is the sharing of a common power source.
A close to exact relationship between them for any given set of steady-state
conditions is discoverable through measurements. Common mode conditions
and differential mode conditions during transmit are related, by definition.
(Take some Benedryl for those itching teeth.)

P.S. If you are of European descent, more than likely

Which probably implies a lossless antenna system.

Any particular reason you want an end-fed wire? A 1/2-wave center-fed dipole works well on 6 meters. The formula is...

overall length in feet = 492/frequency in megahertz

It'll be about 9 or 10 feet long, including both legs. Feed it with coax. No balun really needed. If the SWR is too high, shorten each side an inch or two at a time until it's where you want it. There isn't much directivity to an attic dipole, so orient it to any direction you wish.

I don't think anyone has seriously claimed that any arbitrary antenna
system is reciprocal, truly or otherwise.

Quoting from Kraus "Antennas", 2nd edition, pages 409-410,

*****

This theorem [reciprocity theorem for antennas] as applied to antennas
may be stated as follows:

If an emf is applied to the terminals of an antenna A and the current
measured at the terminals of another antenna B, then an equal current
(in both amplitude and phase) will be obtained at the terminals of
antenna A if the same emf is applied to the terminals of antenna B.

It is assumed that the emfs are of the same frequency and that the media
are linear, passive and also isotropic.

[end quote]
*****

If one tries to add real-world conditions to this ideal system then all
reciprocity bets are off.

As usual, this thread was not arguable in its original form, so it is
quickly drifting to an ill-defined topic that can be argued ad nauseam.

Antenna reciprocity has absolutely nothing to do with anything beyond the
feedpoint. Most of you are confusing what might be called system
reciprocity with antenna characteristics. A couple of you have realized
this, but not yet expressed it in simple terms. System reciprocity and
antenna reciprocity are not necessarily the same demon.

My first thought? Get another wife! Since you don't necessarily want to do that, why not use a dipole? What ever you use, 6 meters has a tendency to make life hard on nearby TV sets, even those hooked to cable. The use of high-pass filters is a given. Good Luck.

I'm surprised they gave you a choice! The REA specifies URD (Underground Rural Distribution) as the norm. And over head lines require special permits in most states nowadays. Lastly, I'm surprised it's 6kv. Typically, it's either 7,350 or 13.6 kv. In any case, URD is the way to go.

Doc
I think the question of height falls into what you are trying to accomplish. Being a COMPROMISE I would say you need to first define what band(s) you want to focus on. My guess is that round 30-35ft you are maximizing it for 20m (lobe wise) , for 20ft at 15m, at 50ft+ for 40m.This guess is based upon lobe patterns for halfwave dipoles. Above 1/2wl you start getting odd lobe shapes. On 80m it is pretty much a NVIS antenna unless you short the feedline wires and feed it as a top loaded vertical.

Probably the BEST compromise antenna (in my limited experience) is an Inverted-L. Reason being is you have both high and low angle lobes generated together so which ever is the most effective lobe you have it available. I think of it as an automatic antenna switching circuit in that I have both a vertical and a horizontal antenna working at the same time.

The reason for the loop is that in my guestimation is that the more wire up the more signal (transmit and receive) and this seems to be verified by various user reports and the slight gain figures EZNEC predicts for the 80m loop on the upper bands.

It appears to get back to the basic question what type of operation do you do and which antenna(s) help you to achieve it.

Doc, I would probably agree that if you have 50ft high loop in most situation height is better (to a degree). If I had capability of the 50 ft I probably would take full advantage of it too (smile). I just wish installing power poles was not so expensive. Up here outside Seattle a set of 4 would run almost $2000. Used poles are only $0.50 a ft but installation crews are a killer

>
>Best regards, Richard Harrison, KB5WZI

Thank you Richard,

As I mentioned, not a very complex issue, but certainly a complex
effect. The follow-on question to consider is now that it has been
shown that the center-conductor is the Common of the Common Mode (for
a free space example) the current distribution on that same wire is
different than it would be for a balanced feed dipole (which gives
rise to a change in the launch characteristics suitably re-inforced by
the "new" Common Mode radiator).

It would have been sadistic to then ask Cecil to confirm the Common
through measurement. Even with a tall ladder, free space is a long
way up to climb. ;-)

However for the earth borne (in more ways that one), confirmation
"should be" simpler. That analysis remains to be explored. Hint,
this relates to the nature of knowing the Common of the Common Mode in
that the Common is not always "fixed" to earth (and has no need to be,
as this is simply a semantic device that carries a lot of unstated
associations as baggage for the unwary).

>

Hi Jeff,

Certainly if the receiver/transmitter faithfully reproduced the
signal, the result at the origin of the sound would be weak - however
many dB down suggests simply turning up the gain (haven't you seen
Dune?).

I recall that back in the 60's the French experimented with a sonic
weapon. The problem there (and typically French) was that it
scrambled the brains of the operator. C'est ca....

You are right to say this is not running time backwards, that would
suggest the effect of the reversal would lead to an "implosion."
However I might guess that a fish at that site, that survived the
original to only experience the reverse, would think (in fish
thoughts) Deja Vu.

One additional thought for the conduit....seal both ends with
"foam-in-place" insulation. Those little rhodents (that will cause my cat
to destroy half the basement catching) will climb up the cables and then
follow the pipe right on into the house. Of course the same is true, where
ever you bring in cables. Don't leave holes for critters. Give 'em a chance
and they'll move right in and take up housekeeping.

I figured with near a 100 foot run that is nearly full and comes out of the
Hoffman Box at nearly 4 feet above the gound would be safe. Wrong! It was
like putting out a sign, "Enter Here!"

It's a QST article by Al Bruxton, W8NX. I think it's on the ARRL website.

I experimented with double-coax traps in search of higher Q and a different LC ratio, but was disappointed. In order to get a reasonably square 40 meter coil using RG-58, the coil diameter has to be over 3 inches, resulting in a much heavier trap. The two pieces of coax must be as identical as possible to avoid shorted turn effects, and adjustment is a real pain because two cables need to be trimmed.

Reg's program works like a champ, and his predictions for 40 meter RG-58 traps on 2 and 2-1/2 inch formers match my actual experience very closely.

Source record: 139079

Hi Steve, well I would leave the two horizontal loops up just like you have them installed. There are several reasons that the 80 horz loop may not be working as good as the 40 horz loop. First, let's examine the feedpoint. If the 80 loop is a square config. then on the upper bands
and having a corner feed, you will experience a rhombic effect that leaves
your signal both incoming and outgoing pretty much in only 2 directions.
I would feed the 80 at 10 to 15 feet away from a corner, But Not at the middle of a side (swr is very uncontrollable, here). Second, loops don't get signal heartburn over trees. They are one of the few antennas
that perform wonderfully in the trees and folage. Third, leave the 80 meter horz loop up at 50 feet, but, if it is possible to just simply lay
a reflector loop on the ground and under the 80 loop. This loop counterpoise can be the same length as the upper loop or you can make it not over 3% longer. By laying on the ground it is going to look electrically longer anyway. You will notice some difference in tuning the antenna coupler, and give it a try on the air on any of your
favorite bands. Normally you will see a difference, and the 80/75 meter
band is going to seem a little longer than normal. Not to get into the subject here, but you can also put a remote L-network on the counterpoise and do some interesting changes to the takeoff angle.

Hope this helps...73...Walter, AG5P

Maybe not. Bill Orr's column in Ham Radio had several different
submissions on the subject in the early 80's. All were US hams, as I
recall, and there was some variation. One was a "three legged dipole" on
75/80 using one wire cut to the center of the band hooked to the coax
center conductor, with two other wires hooked to the shield, one 5%
longer and the other 5% shorter. Gave a pretty good useful response
pattern across the entire band. I used that with three stainless steel
tower guys as my sole 75/80 antenna for years. Worked well.

Yup. I've some 2" in place right now that is plenty big enough to
hold the additional I want to pull thru it, but the way the existing
cable is lying on the corners, I can't get the new ones to go thru.

Source record: 139087

Vito, the ARRL handbook and antenna books all feed horz loops with
coax, even on a multiband use. As for myself, the only coax used is
for
a very few short jumpers from rig to antenna coupler/swr bridge and
the antenna feeders are twinlead or ladderline. Loops are no different
than other antennas in that (unless it is a 1,000 ft loop or larger)
there
are going to be awesome swr challenges in a multiband use, so why not
cut the losses and the extra expense of the coax also makes the
twinlead / ladderline very attractive.

Your concentric near-square horizontal loops, all fed by one feed line
will work just fine, just like a quad beam driven element, however,
you would probably see less interaction between the loops when
you are tuning them up and on the air if the unused loops were
grounded. Since you are basically using monoband loops the coax
feed will do the job but it is difficult to get the correct impedance
transformation piece of 72 ohm coax for the 50 ohm system that
will make your transmitter happy. Since you are more than likely
going to still have an antenna coupler in the line, then my preference
would still be using twinlead / ladderline. And since they are
monobanders, I would feed them mid-way on one side, just like
a quad driven element.

Maybe some of the other folks on here will jump in and help out
with your question.

647. TV Interference Problem-vertical lines???

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-08 21:33:17 UTC
From: mouln@yahoo.com
Message-ID: <30da9028.0207081333.52cde402@posting.google.com>
Source record: 139088
Cross-posted to: rec.radio.amateur.antenna,misc.consumers.house,rec.video,sci.electronics.repair

I have a TV interference problem that's driving me nuts.

I've been getting vertical interference lines on the weaker VHF channels in my area. (antenna reception) It does not affect UHF. The vertical lines appear slightly to the right of the center of the screen.

The lines are subtle on the stronger stations, but pronounced on the weaker stations. The strongest broadcast VHF station in my area shows no interference lines.
The same lines ALSO appear on cable channels except more subtle than on VHF over the air broadcast stations.

The lines DO NOT appear on the screen when using my DVD player.

I cannot identify the source of this interference as an electrical appliance in my house.

Any techies who might speculate what's causing this problem???

One problem is all of the nulls.

Multiple nulls increase problems with fading, and lower system
reliability when the lobes are not broad-nosed and in the correct
directions.

It is common to point out the "gain", despite the fact right next to
each gain peak is a deep null with high "loss" in a direction.

I'll take a clean pattern any day over one with multiple close spaced
nulls and narrow nosed lobes, as long as avaergae gain is the about
the same.

>is. That you don't know what it is, is irrelevant to reality.

The problem is not me, I understand how these systems work quite well.
I was the first one who ever posted on this newsgroup that moving the
balun on a floating network provided no improvement to balance
problems.

The problem is explaining such effects to casual experimenters trying
to determine if a system has common mode problems, or who are trying
to correct those problems. Examples are small loops, dipoles, EH
antennas, end-fed verticals or wires, etc.

I am not allowed to use the term "unrelated" or "not related" in the
context of any specific discussion, so any ability to get into how the
system works is thwarted by a series of endless arguments about the
words "not related".

Somehow there has to be one simple sentence or phrase that tells
people the differential impedance is not related to what the system
might have for common mode impedance.

You are in control, because I have neither time or energy for endless
pointless arguments.

I am begging you for an acceptable phrase or word that you will be
happy with, so I can address specific technical issues without being
badgered by you and Harrison.

Please help me.

The reciprocity theorem apparently requires a conjugate match.
Where is the conjugate match with just an antenna? How can
you compare transmit to receive without a transmitter and
receiver? Without a transmitter and receiver, what is the
meaning of transmit versus receive "reciprocity"? For a
center-fed antenna, removing the feedline drastically
changes the antenna characteristics so what is the meaning
of "reciprocity" after we remove the feedline?

>Hi Tom,
>
>Tell me more.

Take for example a small vertical, like the MFJ, Hygain, or CushCraft
verticals.

The "across" impedance at the feedpoint might be around 50 ohms with
modest voltage, but the voltage from that point to earth can be dozens
of times higher than the across voltage. This is a huge problem with
antennas like the R7, and is a real show stopper if the designer tries
to use a conventional balun.

The most simple circuit analogy to antennas like this is an
autotransformer with an off-center tap, and the load at the upper end
between the two upper terminals.

Like this:

Gen A-------Top
2 turns
Gen B-------tap
10 turns
Ground--------Bottom

As you can see, excitation with only 5 volts of differential voltage
on the transmission line feeding the top and bottom will result in 25
volts of common mode excitation to terminal B when terminal B is
grounded, or 30 volts if A is grounded.

In practice, MANY antenna systems behave like this. Some are even
designed to take advantage of this effect. One example is the
Reflection Beverage antenna when the common mode is used to gather
signal and a low impedance transmission line is used to provide the

transmission of that signal back to the near end of the antenna, where it is terminated or fed to a receiver.

The EH Antenna is designed like a Reflection Beverage, hence my warning that kicked this latest round of shelling off.

There are many other examples, but these are enough to illustrate the problem.

Pay particular attention to Harrison's response that was already posted, because his response demonstrates with crystal clarity how people who think differential voltage is always in a fixed relationship to common mode voltage can get into trouble.

What I'm looking for is a way to tell these people that the common mode voltage can be ANYTHING, and does not have a universal fixed relationship, to differential mode voltages. Feel free to substitute the words impedance or current for voltage.

I generally run into a few people a month who do not understand this basic concept.

Given the Webster's definitions of "not" and "related", it is obvious
that they are at least a poor choice of words and at worst misleading.
You may well have had a definition in mind that differs from Webster's
but if we don't honor standard definitions, communications is impossible.
And I apologize for getting testy with you.

> Somehow there has to be one simple sentence or phrase that tells
> people the differential impedance is not related to what the system
> might have for common mode impedance.

Trouble is, they are sometimes related as they are in my well balanced
dipole system. When I made my measurements, I was amazed at just how
related they can be in a well-balanced tunerless antenna system fed at
a choked differential current maximum point.

> You are in control, because I have neither time or energy for endless
> pointless arguments.

I don't want to be in control, Tom, and I cannot hold a candle to your
antenna system expertise.

> I am begging you for an acceptable phrase or word that you will be

Hi Victor,

Usually this problem is associated with the Horizontal Flyback and the high voltage rectifier (a problem with no real solution however). It sometimes appears to be a broad (say 1 inch wide for a screen width of a foot or so) ghost gray line (subtle as you describe) with perhaps some fine features inside. The line is quite vertical and fixed (does not drift across the screen, always appears at the same place). Signals that have a high AGC (strong signals) mask this as it is always part of the display. As a problem it is not one that can be fixed, except through obtaining a stronger signal.

I sunk a piece of 25G in cement in 1962 for a base for a 100 foot tower. In 1985, I sawed it off at the ground and moved. As far as I know, that base is still there and intact. To make it last forever, coat it with an asphaltic coating and PVC tape, as is done for metallic conduit in cement in the ground, before covering it with cement. Be sure the legs are open on the bottom so condensation and leakage can drain. This is typically done by putting a couple of inches of sand in first, and suspending the legs in the sand before the cement is poured.

The correct way is to obtain a base system from the tower manufacturer. All the components to be set in cement are solid rather than tubular, and hopefully, more heavily galvanized.

>> the same characteristics receiving as transmitting.
Right,
If one considers an rf path as two rather large copper wires (no loss), as does reciprocal theory, then move the generator and load from one end to the other. Check the voltage across the load each time it is moved. It will be the same each time. That is reciprocal. The rf circuit is reciprocal. The effects of fields, propagation, transmitter power, ect should not enter. If you look at it as a dc circuit it makes sense, but if you add other stuff?
Reciprocal is defined, so the discussion is about external influences changing Reciprocity is??.

Tom, W8JI wrote:
"Somehow there has to be some simple sentence or phrase that tells
people the differential impedance is not related to what the system
might have for a common mode impedance."

Don`t mislead people with false phrases.

I just gave an example of how a W2DU balun could change
differential-mode energy accepted by by the common-mode. That energy was
piped inside the coax to the outside of the coax. Inside the coax it is
differential-mode. Outside on the exterior of the coax, the energy is
common-mode.

Common-mode energy on the exterior of the coax is proof of the coax`s
exterior coupling to the differential-mode energy.

Coupling = mutual impedance = relationship.

Don`t ask for help in spreading error. Desist from further spread of
this stuff.

The only time the modes are not related is when perfect balance exists,
and that is nearly never.

Just admit you are wrong in this one instance, however correct you are
in most instances.

You have to put enough stone in the hole to make sure the concrete
does not plug up the legs by getting int the holes at the bottom of
the legs. Then you pour concrete, and crown the top so water runs off.

If you do that, the tower in the concrete will outlast the tower in
the air.

Source record: 139104

I have recently started turning up the flame on antenna building. I have not used matching coils in the past as most everything I have made was 1/4 wave. I recently put a 1/2 wave 6m vertical on the car and I am very pleased with it's performance.

My question is, when tapping around for the lowest SWR on the coil I assume I have the best impeadance match but the dip or flat SWR comes at 53 Mhz, I will of course extend the length of the antenna since I am looking for 51Mhz but how much does the coil effect the resonance of the antenna. Im not sure if I am using the right terminology but it seems based on all the swr readings I have taken is that no matter where I tap the coil the only way to get it to resonate is to change the length. In this configuration should the matching coil be able to compesate for a long or short antenna? or does it have to be resonant FIRST then transform the impeadance to 50 ohms?

The expression "mutually indeterminate" comes to mind, which is probably unfortunate.

But the thrust is that neither differential mode "activity" nor common mode "activity" (current, voltage, impedance, etc.) determines an "activity" in the other. The systems thus are jointly or mutually indeterminate.

Knowing all there is to know about one does not imply that one thereby knows all there is to know about the other. The notion of "predictability" is buried in there somewhere, as well. If two systems are mutually indeterminate, then the degree with which aspects of one can be predicted from known aspects of the other is small to non-existent.

I do not know if I subscribe to all that, but at least it gives Tom an alternative to "related."

> tuner (transmatch) in the ARRL Handbook.
>
"Some folks" searched the 2002 Handbook quite diligently looking for a formal definition of "antenna tuner" and/or "Transmatch," but found none. [The handbook doesn't seem to emphasize definition of terms. It is interesting
(and unexplained) that they capitalize Transmatch like it was a proper name or trademark.] However, they do describe the functions of these devices, per the quotes below.

While searching in vain for definitions, "some folks" did run across a few interesting Handbook tidbits:

"The antenna tuner's function is to transform the impedance, whatever it is, at the shack end of the transmission line into the 50 (ohms) required by their (sic) transmitter." (p. 19.9)

"Impedance matching networks can take a variety of physical forms, depending on the circumstances." (p. 19.9)

"Over the years, radio amateurs have derived a number of circuits for use as tuners." (p. 19.14)

"...a transmission line can very simply be considered as an impedance transformer." (p. 19.8)

"If there are problems <with a ladder-line fed doublet> (such as extremely high SWR...) change the feed-line length by adding or subtracting 1/8 (wavelength) at the problem frequency." (p. 20.5)

"Such a system is sometimes called a 'center-fed zepp'." (p. 20.5)

Note that elsewhere in the Handbook, they define a "dipole" as a half-wavelength antenna, independent of the feed scheme. (End-fed qualifies.) So by their terminology, your antenna would be a ladder-line fed dipole on 80, but would then become a center-fed zepp on the higher bands. Hmmm. Don't much care for that terminology.

Note also that their description of the "Transmatch" function is NOT the same as their description of the "antenna tuner" function... or (best case), it is awkwardly worded and somewhat conflicted:

"When a matching network such as a Transmatch is tuned properly, it "matches" (that is, makes equal) a particular load impedance to the fixed characteristic impedance of the transmission line used at the Transmatch input." (p. 13.10)

This sounds very much like a balun transformer type of function, which, of course, is entirely different from matching the (transformed) antenna impedance PRESENTED at the end of the line--per the antenna tuner function.

> works OK. On 80m, I use six foot increments.
>
<clip>

In his book "HF Antennas for All Locations," G6XN discusses your type of setup at some length. (p. 62-64) He refers to it as a "resonant feeder"
antenna and/or "tuned feeder" antenna, which seems like appropriate terminology. He also discusses an interesting extension of the idea to TWO (or more?) parallel structures, in which one tuned-feeder antenna operates as a driven element, and the other tuned-feeder antenna operates passively as a director or reflector, in a Yagi-like mode. Interesting.

Thanks Richard,

I tried to keep it up as a running diary, but got behind.
Now my wife and I think we'd like a larger place...but I have so much time invested in the tower and shop while my wife has many hundreds of hours into the landscaping that about the only way we would probably move would be to wind the lottery. Then we could afford to hire some one else to redo what we've done here. <:-)) <sigh> And...if we had that kind of money we'd probably look for a better climate.

They're not all "deadly", but even the ones that aren't can make you pretty
sick.
We don't have those here in the frozen North. We only have the Missauga
(sp?) rattler that doesn't usually get very big, but The guy who lived next
door to my folks (30 some years ago) caught a 4 footer along side the road.

He'd had a flat tire. He changed the tire and when he let the car back down,
He heard the tire leaking. Looking down, he saw the rattler coiled up by
his leg. He was hanging onto the tire iron, but waited (stood very still)
until the snake uncoiled and started to crawl. Then he nailed it with the
tire iron.

Some years later I was trimming the bushes in front of our house when I felt
my arm sting. I thought I'd scraped it on the branches. That is, until I
noted to two neat little holes in the side of my upper arm. It was curled
up/around on one of the branches, very close to a bird's nest. I didn't get
sick, but I was black and blue from almost my elbow through part of my
shoulder. (and it did hurt) Good thing it was just a little feller! He,
she, it? was only about 16 inches long.

670. HOHPL (horizontal loops revisited)

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-09 03:17:02 UTC
From: ardujenski@aol.com
Message-ID: <20020708231702.00721.00003251@mb-mc.aol.com>
Source record: 139111

A lot of our discussion is paralleled in LB CEBIK's article on HOHPL
(Horizontally Oriented, Horizontally Polarized Large Wire Loop Antennas)
http://www.cebik.com/atl1.html
He has some good points and a real cood conclusion and it is interesting his
discussion of going to 2wl on lowest operating frequency.

An excerpt from his article is:
"As a consequence of this behavior, the advantage of the HOHPL will not show
itself in any one contact or in a short period. Satisfaction with the antenna
grows with time and changes in the propagation paths, a successful
communications almost everywhere shows up in the log" LB CEBIK

Here is to some good reading...Alan KB7MBI

That's one of those "It all depends" answers.
It depends on the type of tower. It depends on from that the tower is
constructed, and it depends on how well the tower base is drained and
prepaired. It also depends on how well the base was installed in the first
place.

I've had plain old dirt mounts that were still in good shape after being in
the damp ground (clay)for nearly 20 years. I've also seen bases that went
to pieces in short order.

So, without a bit more information, I can't really give you an answer.

I've heard of that idea, but did not know where it originated.

The OCF dipoles described in the QST article have four "legs", all of different
lengths. Two of them make up a classic 80 meter OCF, and the other two make up
an OCF somewhat higher in frequency. 6:1 and 4:1 baluns were tried at the
feedpoint.

The end result is an antenna that allegedly covers 80/40/30/20/17/15/12 and 10
meters with coax feed and low SWR on all of the bands mentioned.

It's in "The ARRL Antenna Book" glossary. Transmatch = antenna tuner
"a device containing variable reactances (and perhaps a balun). It is
connected between the transmitter and the feedpoint of an antenna system,
and adjusted to 'tune' or resonate the system to the operating frequency."

675. multi-band dipole - newcomer question

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-09 04:50:32 UTC
From: Andreas Hofmann <andreash23@hotmail.com>
Message-ID: <3d2a6b98$1@news.microsoft.com>
Source record: 139116

Well,

Even after studiyng the Antennabook, I am still confused about which multiples of lambda/2 are good to reach a resonant state on another band.

I have a 40 m dipole. very low hanging right now, since I am still in the experiment phase. It is resonant somewhere around 7,000kHz (1:1) (I kept it long for finetuning later).

1. I thought that on any multiples of lambda/2 the antenna is resonant again. But for some reason the antenna does not seem to be good at all on 14,000kHz (1 : inf). It is, however pretty good on 21,000Khz+ (1:2). Can someone explain to me why this is?

2. I am pretty restricted with antennas, due tu CC&Rs. So my dipole is actually a stealth antenna, pretty thin wire. If I had to, I could make it a multiband dipole, by adding one or two parallel dipoles. Adding a total new antenna is probably not a good option in my case. My goal is to get as many as possible HF bands covered with a 2 (maybe 3) parallel dipole antenna starting from 40m up (WARC would be good). I dont care too much about 12 and 10m. Also, an 80m dipole does not fit in my yard.

any hints, tips are appreciated.

Andy, KU7T

hi david
i would check out http://www.directivesystems.com
they sell all kinds of microwave antennas for amature use and commerical
they should have something with high enough gain to suit you
as for mobile i dont think its feesible with any kind of range anyways
good luck

Odd multiples of 1/2 wavelengths are resonant with current maximum points
in the center. Even multiples of 1/2 wavelength are anti-resonant with
voltage maximum points in the center. So a dipole that is resonant on
about 7 MHz will be resonant on about 3x7 = 21 MHz. A 1/2 wavelength
dipole cut for 40m will have an extremely high feedpoint impedance on
20m, not good for coax.

You could also make it a multiband antenna by feeding it with TV twinlead.
With any luck, you could work all HF bands 40m-10m. Just such an antenna
is described on my web page.

how about putting up a ground mounted multiband vertical like the R8 from
cushcraft or something similar and hide it in the back yard or if you are
allowed a flag pole make one out of PVC pipe and hide the vertical inside of
it
that way you will get all of the HF bands with not much trouble
good luck

> under ground and used 2"

Applying the general rule from the electrical code, total
cross-section of the cables shouldn't exceed 40% fill (of the
available conduit area). That allows no more than nine .405" OD coax
cables in a 2" ID conduit.

The practical limit is lower, because you almost certainly will have
complications:
* Long runs,
* Curves,
* Connectors on the cables,
* Etc.

Besides, it's a real pain to dig it up and replace it if you outgrow a
smaller conduit.

And matching of any 1:1 junction is totally unneeded. So?

SWR doesn't have to be "high", just higher
> than 1:1. You can use 75 ohm coax to convert 112.5 ohms to 50 ohms
> because the SWR is not 1:1. It is 1.5:1. 112.5/1.5 = 50*1.5 = 75
> All series section transformers carry an SWR above 1:1.
>

So you're saying that all matching relates to SWR and impedance is only
incidental?

> Most of the authors probably assume that you can read a Smith Chart, Dick.

I seriously doubt it, given that all my electronic training as well as
study for all levels of both amateur and commercial FCC licensing
contained no reference to the Smith Chart. Not once did it ever show up
in a test.
It is noted in some texts that the Smith Chart is very useful for "RF
designers". That makes it useful for engineers at any level. So far I
have done no design where I needed the Chart to do any matching. Yes, it

would come in handy and useful, but it isn't needed for the successful design, installation nor operation of normal ham radio antenna systems. Frankly I would have learned it anyway had it not been such a involved subject that I have yet to find a text or other publication that treated the teaching of the Chart in any practical fashion. Invariably engineers seem unable to present it in a way that can be readily absorbed by most ham radio operators, even most of those who have a technical background. Why this should be is obscure to me, but most writings on the subject deal with the interminable details of discussing at length all the Chart's attributes and never get around to actually dealing with how the chart can be used on a practical level by practical people-if indeed it can be. That makes it particularly difficult for non engineering people to learn the operation of the chart. Your last post on the subject sheds no light whatever on the subject.

In fact I would like to learn how to use the chart even now. If anyone has a lead on a good tutorial which actually gets to the use of the chart without all the engineering explanations that always accompany most descriptions of it I would be interested.

Overstates the case I believe.

Two balanced telephone pairs. The signal in one pair is measurable in the other pair because balance is imperfect.

We don`t know in advance exactly how much cross-talk we will have but we can measure it as built. Predictable and determinable are not the same thing.

You have to put enough stone in the hole to make sure the concrete
does not plug up the legs by getting int the holes at the bottom of
the legs. Then you pour concrete, and crown the top so water runs off.

If you do that, the tower in the concrete will outlast the tower in
the air.

I challenged Tom to show his work. Instead he reposted mine.

Ohm says; P = E squared over R.
Tom specified "several hundred volts"
I picked a resistance of 50 ohms as most transmitters are designed for
this load.
300 volts qualifies as "several hundred volts".
P = 1800 watts, hardly QRP.

Tom should show how he would get a different answer.

Best regards, Richard Harrison, KB5WZI

I'm saying that all series section transformers carry an SWR greater than
1:1. If it doesn't carry an SWR greater than 1:1, it is not a series section
transformer - it is a "flat" section of line and is not doing any impedance
transformation.

You keep saying the present exams are easier than they were in the past
but the Extra exam I took and the present Extra exam contain questions
on the Smith Chart.

> In fact I would like to learn how to use the chart even now.

Do you know how to plot impedances on a Smith Chart? It's hardly any
harder than plotting points on a graph. In fact, a simplified tutorial
on the Smith Chart might be interesting to a lot of people. Would you
be willing to participate in a thread titled, "Smith Charting Made Easy"?
That's a half finished magazine article of mine.

Here's where you can obtain a Smith Chart from the web.

Dear 'Doc,

Thanks for the reply.

Isn't a transmission line a transformer? Don't mean to be too picky
but any transmission line performs an impedance transformation unless
it is n * 1/2 lambda at the operating frequency. A tuner doesn't make
the antenna resonant, I agree, but is does make the antenna system
(antenna, transmission line, tuner) resonant, doesn't it? I can't see
how a transmission line is different from a lumped impedance tuner.
You seem to imply that there is some sort of real difference. What is
it?

If I am wrong I'll tear up my Smith charts and start again. ;-)

For 500 MHz of bandwidth you'll have to sacrifice gain and for that much bandwidth you don't have a lot of good choices. A log periodic is the logical alternative.

Source record: 139037

I had missed this artilce in LB CEBIK's website but talks about HOHPLs (Horizontally Oriented, Horizontally Polarized Large Wire Loop Antennas) but it does address many issues we discussed here
http://www.cebik.com/atl1.html
An interesting part of his conclusions is QUOTE:

"For nation-wide and world-wide communications, evenness of pattern may often be more important than the gain of one or more individual lobes. As a consequence of this behavior, the advantage of the HOHPL will not show itself in any one contact or in a short period. Satisfaction with the antenna grows with time and changes in the propagation paths, a successful communications almost everywhere shows up in the log" .... LB CEBIK

looks like I need to be planting those poles for the corners (smile)

The definition of a transmission line is different from a lumped
impedance tuner. From the "ARRL Antenna Book":

"Transmatch - antenna tuner - A device containing variable reactances
(and perhaps a balun). It is connected between the transmitter and
the feedpoint of an antenna system, and adjusted to 'tune' or resonate
the system to the operating frequency."

Source record: 139043

Hi, all.
I am trying to build a relay-operated antenna switch for HF.
I threw together one in a 4x4x1" box with 2 so-239 connectors on
one side, a bnc (for the common) on an adjacent side, and a "mini" relay
from radio shack to do the switching.

I wanted the unused antenna grounded, so I'm using a DPDT relay.

The swr through the switch into a dummy load is around 1.3:1 to 1.4:1
(on 20m). My ts-850 starts limiting output around 1.5:1, so that doesn't
leave much room for swr in the antennas.

How can I design / build a switch that has a lower swr? I know the relay
adds some, but even hooking an so-239 directly to the bnc gives me about
1.2:1, so hopefully I can design the box better.

Would I have better results with an older-style open-frame relay?

Thanks for your ideas.

Go to an electrical supplier and get a couple cans of cable pulling soap (usually an ugly bright yellow). When you go to pull in another cable, liberally coat the new cable with the soap. Acually you fill your hands with the stuff and pull the cable throught them.

Considering you already have cables in the conduit without the soap, you might want to take a quarter inch rope and pull it through a few times after liberally soaping it up.

If it's only a few feet to those cornerswhere the cable hangs, you might try attaching a 1/4 tygon tube to the soap can and thouroughly soaping the corners as well. With the corners, old coax, and new coax soaped up well, it will just push the old coax over and slide right on through.

With *things* liberally soaped up, you can pretty much put the 10# in the 5# bag, so to speak. We've pulled so many wires through a conduit that there was a guy at each bend, plus about every 10 feet beating on the conduit (steel in this case) with a hammer to pull through more. When taken out some years later, they looked like they'd been molded into the pipe.

I just did a recount and I have 6 LMR-400 and 6 RG8X size coax cables which includes one with two RG-6 coax cables and the control cable for the C-band satellite dish, and 3 rotor cables (one for rotor and two for switching) through 3 inch conduit.
I could probably squeeze in another three, although I'd like to make two runs of LMR 900 (if the stock market ever comes back up)

Just don't forget the soap! It not only makes pulling in more cables a breeze, it's much easier on the cables themselves.

Don't be afraid to zig-zag the wire (especially at the ends). If you could get up 120' of wire and feed it with 450 ohm line, you would be ok.
To minimize losses, you could use 14 gauge ladder line. (BTW, Ladder Loc is a great product.)

How about a mast on your chimney to get the center up around 35'?

Apparent, Andy (KU7T) in your answer to Dennis' question, you've never seen an R8. It really IS NOT a ground mounted antenna, and if you do mount it on the ground, it won't work very well. It is technically a loaded 1/2 wave and needs to be clear of surrounding objects including the earth. I tried for 4 months to get one to work as advertized, and finally Cushcraft replaced it with a new one. I gave it away!

As for disguising it inside a chunk of PVC (aside from the above statement), the PVC would be about 10" or 12" in diameter. Obviously not an ideal flagpole.

Sorry.

You can't use the VSWR readings to establish resonance. Unless you're very lucky, or the antenna ground and coil losses are large, the input won't be 50 ohms. You can use a full 1/4 wave on 6, and infact several folks make 5/8 wave verticals for 6 meters, something you can't do very well on 80 and 40!

You need to invest in a good antenna bridge. The best bang for the buck is the 259B MFJ (269 has UHF added). There are others, too. This way you will know both the resonance point, and the VSWR at that point.

If you can find an older issue of the Mobile Manual, say circa 1960 to 1965, therein was published a good homebrew 6 meter 5/8 wave vertical. At least it'll give you a place to start.

Fun isn't it?

Tom is correct. Just make sure that any water gets into or condensation which forms inside the tower legs can drain, and you'll be OK. Sand and then a stone layer works well. The advantage of using a folderover base should be obvious, but it has a little less strength.

Andy,

I am using multi-band dipoles as well. I have found that 1. the number of dipoles must be limited to no more than antennas, and 2. the resonant frequency of each will be about 10% lower than that calculated due to the proximity of the other wires.

Hello Alan,

Claims of antenna performance should always be taken with a grain of
salt unless there is "hard" data. For example, some hams would
consider a Field Day setup that averages 20 QSOs per hour using a 100
W rig to be doing really well, while another group would consider that
same setup to be unproductive.

> I got a copy of EZNEC DEMO and played with various size loops and heights. I

>
> I am not too sure if my modeling was too crude to be of value.

EZNEC is wonderful but the demo version limits you to 20 segments. For
a model to be accurate, segments must be less than a certain fraction
of a wavelength - otherwise errors develop.

A 270 foot loop of wire that uses all 20 segments will have a segment
length of
13.5 feet - almost a quarter wave on 20 and almost a half wave on 10.
The accuracy of such a model is somewhat doubtful.

Also, you might want to compare the loop model against other antenna
types before making a decision. Your 95 x 110 foot lot can fit a 130
foot dipole or inverted V diagonally. You might consider comparing the
patterns and gain levels of such a dipole or inverted V vs. a loop.

Look at the following site:

http://www.iol.ie/~bravo/remote.htm

In particular look at his suggestions for modifying the relays.
I did this for a 3-way switch I just made, and it seems to work
pretty well.

Tim, KA8DDZ wrote:
"---I assume I have the best impedance match but the dip or that SWR comes at 53 MHz."

Resonance is elimination of reactance in the antenna at a particular frequency. The antenna becomes a resistance that usually does not match your coax surge impedance. A mismatched resonant load produces SWR on the transmission line An impedance transformation is required for an SWR of 1:1.

Best regards, Richard Harrison, KB5WZI

Harrison,

Quit being so silly. I allready posted a response to Richard Clark
that gave an example.

All the silly pointless attacks accomplish is to show you don't
understand the problem at all, and prove my point that some people
need a clear single-sentence phrase to help them understand that the
differential mode conditions, including voltage, do not have a fixed
relationship to common mode volatges.

Read my earlier example.

Rediscovering the ZENNECK Surface Wave

In 1916 while speaking of his system for global
transmission, Nikola Tesla cited the analysis of
mathematician Arnold N. Sommerfeld as verification of his explanations
of observed radio phenomena.
Tesla was referring to his system in which 90% to 95% of the
electrical energy was manifested at the
transmitters output as "current waves" with the remainder directed to
the antenna structure, resulting in
dissipating EM radiation.
In 1909 another investigator by the name of Johann Zenneck,
while working to explain Marconi's
transoceanic results, showed that a unique type of surface wave could
travel along the interface between the
ground and the air. In the words of Dr. James Corum, "The
distinguishing feature of the Zenneck wave was
that the propagating energy didn't spread like radiation, but was
concentrated near the guiding surface.
Sommerfeld had shown that an electromagnetic wave could be guided
along a wire of finite conductivity,
and Zenneck conceived that the earth's SURFACE would perform in a
manner similar to a SINGLE
CONDUCTING WIRE."
In commenting on Sommerfeld's analysis of the surface wave,
Dr. James R. Wait states that "The field
amplitude varies inversely AS THE SQUARE ROOT of the horizontal
distance from the source . . . " It is
interesting to note that Sommerfeld made a point of distinguishing
between the "electrodynamic" SURFACE
WAVE and its Hertzian counterpart the SPACE WAVE, believing that both
components could be present in
VARYING PROPORTION in the WAVE COMPLEX. It was Tesla's assertion
that the exact composition
of the emissions was dependant upon the design of the transmitter.
As the study of radio propagation progressed and certain
mathematical analyses EXCLUDED IT, some
question as to the existence of the Zenneck surface waves began to
develop. In 1937 limited supports was
given to these doubts after tests showed SIMPLE ANTENNAS driven at
150mHZ produced 100 times
LOWER field strengths than predicted.
More recent investigations show evidence that Zenneck waves
can, indeed, be generated. The LOWER

the frequency, the lower the PROPAGATION LOSSES.
It is also apparent that they are NOT major contributors to
the field produced by an electric dipole or
quarter wave RADIATOR. However, they can be strongly excited by a
quarter wave RESONATOR! Once
again to quote Dr. Corum, "the resulting wave is a SURFACE GUIDED
(single conductor)
TRANSMISSION LINE mode which attenuates EXPONENTIALLY ALONG THE
GUIDE . . . There is
NO INVERSE SQUARE spreading or DIFFRACTION, as with Hertzian waves .
. . With appropriate
constitutive parameters, a pure Zenneck wave would seem to hold out
the promise of GUIDED
PROPAGATION with NO radiation field to WASTE ENERGY."
Plots of field strength vs. frequency indicate that a
Zenneck wave propagates best at ELF and VLF
frequencies and would lose much of its advantage as frequency rose
ABOVE 1mHZ.
A new Russian magazine AURA-Z was published almost one
year ago. On the back cover was an
advertisement for papers describing a 'new' effect that had been
discovered for the transmission of power
over a single very fine wire.
The wire could be cut and tied in a bow, yet the power still
flowed over the wire. It used something
called a 'monovibrator' to produce the peculiar wave necessary to
achieve this effect. There was no technical
data except for that offered in the papers for $100.
Power transmitted over a wire (note over, not through) is
subject to dissipation through impedance,
capacitance, inductance and resistance.
Hooper showed that a moebius coil could produce what he
called a 'motional wave' or a wave of
PURE ELECTRIC CHARGE. When energy moves through matter, it is sapped
capacitively (electrostatic)
and inductively (magnetically).
The pure electric wave was not sapped in any way and so
could be transmitted over enormous
distances with no signal loss. Propagation of such a signal through a
transmission line or conductive path
apparently takes the form of successive solitons that regenerate their
spherical pattern much like a smoke
ring vortex. It is an enfolded structure consisting of high rotation
energy in the doughnut shape.
This ties in with Walter Russell's claims that energy rings
form, transmute and destroy matter, as well
as with Larry Spring's claim that energy propagates through space in
the form of successive spheres as he
had measured by field strength mapping of fixed frequency
transmitters.

The point here is that everyone is using similar terms and
concepts to describe the same thing. The
bottom line will be a circuit which we can all use to verify the
truth of it and then put it TO PRACTICAL
USE in doing real work.
According to the information published in the Russian
magazine INVENTOR AND
DEVELOPER, a new opportunity to transmit electric energy has been
discovered.
As it was demonstrated by scientist Vladislav Avramenko at
the Russian (former All-Union)
Electro-Technical Institute in Moscow, it is now possible to transmit
electric energy through just a SINGLE
WIRE (similar to superconductivity at room temperature). The article
does not disclose the details of the
method. It does say that the primary power source generates electric
energy in OSCILLATING FORM in the
RANGE OF SOUND FREQUENCIES.
This energy is then transmitted in a regular way to a small
monovibrator (which is the inventor's
secret). Only one wire goes out of the monovibrator. The wire
extremity is connected by means of this single
wire to a small (matchbox size) box. The box has a regular double
contact OUTLET thus providing a power
supply for electric bulbs and other devices. It is disclosed that the
energy transmission through a single wire
occurs when the appropriate frequency (not specified) has been
ADJUSTED (tuned) at the input of the
monovibrator.
If the single wire has been cut there is no need to solder
the ends of the wire; it is sufficient to tie the
separated ends with a bow knot in order to restore the line. They
measured the loss of energy in the single
wire when transmitting relatively HIGH POWER over the distance of 100
meters. It was reported to be
ALMOST ZERO.
The phenomenon disclosed contradicts contemporary accepted
science. But the article claims it works!
This information, if accurately presented, suggests that some type of
scalar-wave transmission might be
involved. A normal electric sonic frequency signal would be unlikely
to travel (or be guided) along a
conductor of 100 m without significant losses.
A scalar field can be generated from just about any type
of energy, sound, electricity, magnetism,
light, etc.. That energy simply has to be IN VIBRATION so that it
can be 180 degree phase reversed to
create the hyper space bubble or the soliton bubble called a scalar
potential or a scalar field, or even a
'quantum potential'. These bubbles can be sent down a guided conductor

as successively driven bubbles for
information or energy transmission.
So, the energy is vibrating at a frequency determined by
the vibration across the diameter of the mass
structure. When this frequency (as in some cases) is phase reversed,
it creates the scalar potential bubble.
The energy disappears from our detection threshold and creates a
stress wave in hyper space. From that
point, it can be sent to a target where it is received, the phase
restored to 3D space coordinates and the
energy is again available for use, all with the minimum diminution of
energy.
The one major problem is our understanding of how to
receive these scalar bubbles. Transmission
appears to be simply a 180-degree phase shift, done with a bifilar
wire to cancel the magnetic component, a
moebius to create the one-dimensional surface (pure electric wave of
Hooper) or a caduceus.
For reception of a scalar potential, the bubble still has a
vibrational component that can be accessed
via resonance. Using a caduceus or moebius antenna tuned to the
frequency of the transmitted scalar bubble,
it would be received but not detectable with normal instrumentation
UNTIL the phase had been restored. It
is best understood as an enfolding process where the wave is folded
onto itself (like a doughnut vortex),
moved to the target, then opened back up.
I have also been told that the scalar is a kind of building
block for all energy. Once the energy has
been converted to the base form of scalar, it can be 'reconverted' to
any type of energy in our 3D space.
Thus, using scalars, you could convert sound to scalar, then scalar
back into electricity or light to scalar,
then back to magnetism.
At this time, I think the form of the re-conversion back to
3D space is dependent on the medium used
for its reception. That is a coil would produce magnetic energy, a
capacitor would produce electrostatic
energy and I have no idea how sound would be produced direct from
scalar energy. There are indications it
is a matter of frequency based on the 'aether spectrum'.
At this point, perhaps these correlations will lead to
something practical. It is not over unity because
we are dealing with power transmission, not generation. Where this
information is useful, is in providing
very high transmission efficiencies approaching unity, but that is a
start...

I pulled thru a continually soaked a terry towel, or actually my
helper did, while feeding in the cable. Things were dripping...

> Considering you already have cables in the conduit without the soap, you

Nope. They are soaped with the yellow teflon (or is it wax?)
-bearing goop. It dries out but leaves a slick film EVERYWHERE.

> might want to take a quarter inch rope and pull it through a few times after
> liberally soaping it up.

That's an idea. My original pull line was 1/4" yellow poly (600lb
test). Also tried some smaller twine but still hung same place.

> If it's only a few feet to those cornerswhere the cable hangs, you might try

About four feet vertical from one end.

> attaching a 1/4 tygon tube to the soap can and thouroughly soaping the
> corners as well. With the corners, old coax, and new coax soaped up well,
> it will just push the old coax over and slide right on through.

My trouble is probably because the old stuff isn't coax. It is 3 *
#6, 9 * #12, and 2 * #10. The 3 * #6 kind of spiraled together as
they were pulled in, and they lay pretty heavy. They feel about as
awkward as if they were a single 4/0 (which I've run 2x in another
pipe). I've put more than 100 pounds on the new bundle pull line.

I'll try getting some goop around at the corner. Also going to have
to try again slimming down the head of my new bundle... Might try
pulling multiple smaller bundles (I'm trying to add another #6 and
12 * #12 ...). Right now it is a really solid "thunk" when it hits

the existing wires in the sweep.

> With *things* liberally soaped up, you can pretty much put the 10# in the 5#

> years later, they looked like they'd been molded into the pipe.

Yikes! They had been molded in. Or hammered! :)

Was that adding new wires into an already full run or pulling a new
bundle thru empty conduit? I've pulled some pretty full initial
loads, but adding more is always worse.

How did you attach the bundle to your pull line? Usually I have
enough room to do a really secure attachment, but not this time. I
tried a long overlap but somewhere over 100 lbs pull the pull
line slipped thru without moving the bundle. :(

> I just did a recount and I have 6 LMR-400 and 6 RG8X size coax cables which
> includes one with two RG-6 coax cables and the control cable for the C-band
> satellite dish, and 3 rotor cables (one for rotor and two for switching)
> through 3 inch conduit.

:) Yeah, larger conduit is much better than multiple smaller runs.
I'm not running anything under 3in for coax. Unfortunately the
electrical isn't that big... (usually 1-1/4in to 2in)

> I could probably squeeze in another three, although I'd like to make two
> runs of LMR 900 (if the stock market ever comes back up)

:(

> Just don't forget the soap! It not only makes pulling in more cables a
> breeze, it's much easier on the cables themselves.

Definitely. I'd never put 100 lbs pull on LMR-400. Who knows what
the impedance would be after that!

You gave me some more ideas and renewed hope. Now I've got to crawl
into that hot attic again.

Thanks!

Source record: 139066

So...the antenna part (your nominally half-wave vertical in this case, fed against the car body as a ground plane presumably) has some feedpoint impedance at all frequencies. It will look like a fairly high impedance (hundreds of ohms), resistive, at resonance, and be reactive above and below that resonant frequency. You can always tune out the reactance by putting some inductance or capacitance in series, or in parallel; your coil can serve that purpose in addition to stepping up the impedance, if the antenna feedpoint is capacitive. You can get analytical about it if you really want: you can find tables or graphs of the feedpoint impedance versus frequency, or use an antenna program to get it...even the evaluation version of EZNEC should do, I think. Then the tapped coil can be thought of as two coils which also have mutual inductance...that probably gets a bit harder to evaluate. Whether it's worth getting analytical or not probably depends a lot on how much effort it would be for you and what you'd get out of it. But I would expect that you could get a good match by using a tapped coil and a capacitor; that lets you have two adjustments (the cap and the coil tap) which you pretty much need to get both the resistive and the reactive part matched. Or, as you note, you can do it with the coil tap and the antenna length. A "trombone" sort of sliding section on the antenna makes that part easier.

Cheers,
Tom

728. Shack resonates at 40M

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-09 23:33:43 UTC
From: cprstn54zz@att.net
Message-ID: <3d2b72d4.17317968@news-server.optonline.net>
Source record: 139068

When I TX on 40M at anything over 50 watts, my smoke detectors set off my house alarm. Also, my shack seems to get a little RF hot at 40M. This doesn't happen up to and beyond 100 watts on any other band, from 160M to 10M. I can measure the field on my Radio Shack field strength meter, which deflects full scale at max sensitivity at 1" from the mic. I do not get a shock from my mic tho, so it is not all that hot.

I am using a sloping multiband dipole. There is a horizontal 40 ft. long metal A/C duct (grounded) pointing at the antenna hub, but 10 ft away from it. My RG-8X coax feed line runs along the length of the duct and 6" away from it. There is also some electrical wiring running parallel to the feed line and 6" away for up to 15 ft.

In addition, there are three vertical steel fireplace flues terminating around 2 ft from the dipole hub -- all of them also grounded. One is 22 ft long, the second is 30 ft. long and the third is 40 ft long (all plus or minus 2 ft). The 30 footer is 1/4 wavelength at 40M.

I believe I am pumping some RF into the house ground at 40 M through the duct, the flues or the electrical wiring. Is my feed line doing it, or is the antenna RF lighting up my duct the flues and my house ground? BTW, before I bought and installed the antenna the manufacturer opined that neither the duct nor the flues would impair propagation. I didn't ask him about other possible problems -- like the one I am experiencing.

I could relocate the feed line away from the duct, but it would then be closer to plumbing lines and other wiring. I could also try disconnecting the duct and flues from the house ground or choking the lead(s) to the furnaces/fireplaces which effect(s) the grounding. Any oher thoughts?

I have seen some postings on solving the smoke detector problem. Should I just try to solve that, or is that just a symptom?

Can you move the antenna around? Is it a good match on 40?
The feedline is likely irrelevant if it's quality coax and matched at the antenna.
Something is resonant. (DUH).....
This is good for antennas and bad for alarms.
Walk around with the field strength meter. TAKE DATA, LOOK AT IT, PLANNING IS CHEAP.
This stuff is always fun. Nature contains exquisite beauty.

If you understand the issue, a simple, elegant solution usually presents itself.
This is physics, after all, not superstition.

Mindless, shotgun "solutions" waste time and energy.
Make sure the fundamentals are correct.

I have a double bazooka on 40 that plays nicely.
My 80 meter bouble bazooka used to set off the alarms 'till I moved it.
This is all at 1200 watts PEP.

> You can't use the VSWR readings to establish resonance.

==========

Sorry to disagree.

If frequency is varied while observing the SWR meter then the resonant frequency is where minimum SWR occurs. The input resistance of the transmission line will then be a pure resistance as it should be at resonance.

But what the won't tell you is whether the input resistance is greater or smaller than 50 ohms. For example: if minimum SWR is 2-to-1 then the line input resistance is either 25 or 100 ohms which is rather a large uncertainty.

Hi Rick,

You may have predicted, but you cannot make a future determination as
you describe without it becoming (obviously) - a prediction - your
statement which then negates itself:
>I [successfully] "predicted" you would resond, Richard,
>but I [failed to predict] never could have determined your

Normally such a short lead (four inches) won't cause problems.

Make sure the ground path is good. Some boxes are folded and painted,
and some have clear anodized surfaces that is a good invisible
insulator.

Also, be sure you use a fairly thick conductor and avoid woven or
finely stranded wire for connections.

Other than that, you might have a bunch of small problems adding up.

Useful as distractors, but not on the question pool only on the test. I understand some vendors don't include distracters in the question pool.

Even my 1951 ARRL License Manual
> contained exact answers if not exact questions.

Yep. One never had any good idea what they were going to ask on the test, so one tended to make darn sure you were ready by learning the information discussed, usually at length, in the study guide also known as the License Manual of the time. Getting an advance copy ot any test was at the risk of FCC fine or jail, and for darn sure disqualification for any ham radio license.

In fact, a simplified tutorial
> > > on the Smith Chart might be interesting to a lot of people.

I've long believed just that. The writings I've seen to date all seem directed at engineers who are already pretty well familiar with the details involved. I haven't had a chance to look over the stuff I downloaded and printed today in any detail, so there may be something different in it, but a tutorial from the beginning would be a welcome change.

My MFJ-259B indicates the lowest (50 ohm) SWR is not at the purely
resistive point and I don't know why.

I'm not saying these measurements are correct, Reg, just reporting
what my MFJ-259B says. For my antenna system, it says minimum SWR
occurs when the resistance is 42 ohms and the reactance is 8 ohms.
It says the purely minimum resistance at resonance is 21 ohms.

50 ohm SWR for 42+j8 is 1.3:1 at 7.120 MHz

50 ohm SWR for 21+j0 is 2.4:1 at 7.015 MHz

The MFJ-259B is reporting that the resistance is changing with frequency
much faster than the reactance - for a one wavelength dipole fed with
3/4WL of ladder-line on 40m - so that minimum 50 ohm SWR does not
occur at system resonance. Could this be a function of an antenna
operated at the voltage maximum feedpoint.

The loop is "balanced" because the impedance referenced to ground
is close to the same looking either direction at the feedpoint (as
it also is with a dipole).

746. Making a flexable handheld VHF antenna, any ideas?

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-10 03:17:13 UTC
From: grant <5@6.7>
Message-ID: <ZGNW8.32071$P%6.2623817@news2.west.cox.net>
Source record: 138988

Hello,
I am interested in finding out how to possibly build flexible handheld VHF antennas.

Any of you here done this before?

I have been given some suggestions as to using something like speedometer cable housing for the casing and also using guitar string for the antenna element wire. Cut the wire to the appropriate length and solder it to the BNC connector. Put it in the housing. Possibly epoxying the base or using glue filled heat shrink to stiffen the base and cap the top.

I am looking to replace an antenna for a VHF marine band radio. I bought this 15" flexible antenna http://members.cox.net/radiocheck/Antenna.jpg , about ten year ago from a marine electronics store called Neptune Electronic in San Pedro. It had no packaging at the time, and was just under the glass counter, and they said it was for the VHF marine band. It has been MUCH better than the stock 7" flex antenna that come with the Standard Horizon HX220S that I use, and as you can see from the picture it gets used a lot at work. In fact part of metal are falling out of the BNC connector on the antenna.

I could use a 30"(approximately) metal telescopic antenna which I have and get even better reception, but the length and stiffness of such an antenna breaks the BNC fitting at the top of the radio if the radio is moved around to much or to quickly as I do at work. So this 15" flexible antenna has been perfect because it is thin and light, but flexes if hit or the radio is jarred, and I move around a lot at work and need to have the radio with me. So I've also been thinking that the building materials could be something like using a bicycle break/shift cable housing, and using some good copper wire for the element. Any ideas as to what would be the best housing and element material, so that it would be as thin as possible, light and still flexible? And I really need this longer antenna because I need/like to hear stations that are well away from the harbor at times, further away than the stock 7" will receive.

These VHF FM marine band radios use a frequency range of 156.2500 - 157.4250 (plus 161.8000 - 162.0000 for "marine operator" repeater outputs). And this Standard Horizon has a transmit power of 1watt and 6watt.

I gotten a formula for cutting the wire to the appropriate length and here it is:

Now I don't know much about this stuff yet. And I am just assuming that I understand the 1/4, 1/2, 1/8 wave idea. Correct me if I'm wrong.

So using 156.800 (channel 16) as the frequency I get:

1/4 wave; 234 / 156.800 = 1.4923469, then x 12 = 17.908162, then x .8 = 14.326529
inches.

1/2 wave; 468 / 156.800 = 2.9846938, then x 12 = 35.816325, then x .8 = 28.65306
inches.

And looking at the math going on here I just assumed the a typical stock 7-8" antenna is 1/8 wave. Again, correct me if I'm wrong.

And going up in length gets proportionally better reception. Does that also mean the transmission gets better as well? Again, for my handheld, I want reception as the key feature I want out of it. After I hear someone calling for assistance I can run to the boat for best transmission on the fixed mount VHF marine radio if the handheld is not getting through to them.

Now there are antennas on the market that sold where they say that they "cut length to frequency". And some of those out there that look interesting to me are said to be "base loaded", and end up being not quite as long as a straight element antenna. One company called Smiley Antenna makes a model called the "5/8 Slim Duck" http://www.htantennas.com/2meter.htm that is base loaded. Would an antenna like this be better than a straight element antenna? Is making a "base loaded" antenna possible?

Well enough for now. Any Ideas?

Grant

747. Solving a problem with the Smith Chart

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-10 03:29:09 UTC
From: CAM <w5dxp@hotmail.com>
Message-ID: <3D2BAA05.5C3221C3@hotmail.com>
Source record: 138989

This is for Dick and anyone else who wants to observe the usefulness of the Smith Chart. Here's a real world problem for us to solve. The G5RV is a poor performer on 30m. Let's use the Smith Chart to diagnose why and modify that G5RV to perform well on 30m.

Position a Smith Chart in front of you so the only straight line on the chart is horizontal with 1.0 in the middle and 2.0, 3.0, 4.0, ... to the right. The Smith Chart is a graph upon which complex impedances can be plotted. That horizontal line is the purely resistive line. All impedances with zero reactances can be plotted on that line. Note that all the way to the left on that horizontal line is zero ohms and all the way to the right on that line is infinite ohms. Since all common resistances fall in that range, we can plot any resistance in the world on that line.

The Smith Chart is normalized to a certain characteristic impedance, i.e. the characteristic impedance (Z0) of the transmission line with which we are dealing represents that 1.0 in the middle of the Smith Chart. For our G5RV example, the Z0 of the twinlead is 300 ohms. Thus, the 1.0 in the center of our Smith Chart will represent 300 ohms. All resistances less than 300 ohms will fall to the left of center on that horizontal line and all resistances more than 300 ohms will fall to the right of center on that horizontal line. Zero ohms is still all the way to the left and infinite ohms is still all the way to the right on that horizontal line. For all points on that horizontal line, the reactance is zero.

In order to plot points on our Z0=300 Smith Chart, we must normalize the different impedances to 300 ohms. That means simply dividing the impedances by 300 ohms. So 300+j0 divided by 300 equals 1.0+j0 and represents the point in the center of the Smith Chart. 50+j0 on a Z0=300 Smith Chart becomes 50/300 = 0.167+j0. 1500+j0 ohms on a Z0=300 Smith Chart becomes 1500/300 = 5.0+j0 ohms.

Time for a checkpoint. Normalize the following seven values of resistance and plot them on the horizontal line on a Smith Chart normalized to Z0=300.

20+j0 ohms, 50+j0 ohms, 100+j0 ohms, 300+j0 ohms,

600+j0 ohms, 1200+j0 ohms, 3000+j0 ohms

748. G5RV Question

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-10 03:30:32 UTC
From: KA3MTT <nani@fuse.net>
Message-ID: <uinam0l1e0r53c@corp.supernews.com>
Source record: 138990

Greetings! I have a question concerning my G5RV that I just recently installed. I have my shack in the basement, and my RG-8X runs through a PVC pipe that my builder installed between my walls. The pipe leads all the way to the attic, which is where I have the ladder line part of the G5RV arranged in a horizontal loop configuration. I know you're supposed to have it hanging vertically, but there was no way for me to conceivably arrange it that way. The ladder line then terminates into the dipole part of the G5RV outside at the corner of my roof gable. The dipole portion is approx. 51 feet on each side. I am using an externall antenna tuner and can not get a match on 80 meters and 15 meters. I get a half-way decent match on 10 meters, but the receive side is lacking. Anyone have any suggestions for these bands? Thanks in advance for your time. 73's, Nathan KA3MTT

Tom, W8JI wrote:
"---some people need a clear single-sentence phrase to help them understand that the differential mode conditions, including voltage, do not have a fixed relation to common mode voltages."

Wrong.

For example, take a 1/2-wave simple horizontal dipole center-fed with ladder-line at ordinary height above the earth. Take the feedline off at 45/135 degrees, not 90/90 degrees.

We unbalance the feed by lack of the perpendicular, and create a common-mode.

When we transmit, some unbalanced r-f (with respect to earth for Richard Clark) is likely to appear at the sender to bite Cecil, should he be operating. This energy has made a round-trip, starting as a differential signal and returning as a common-mode signal.

We may enjoy the jeopardy and leave things just as they are.

So long as the transmitter output is constant and no physical or electrical changes are made, the common-mode energy returned to the transmitter will remain the same. The relationship is fixed for this set of conditions.

This is like the voltage divider analogy I gave earlier. It can be reset, but once set, it can be relied upon to retain its position and function.

The common-mode voltage at the sender can be stated as a percentage of the transmitter output voltage. Measurement of the voltages is all that you need to calculate a percentage.

Best regards, Richard Harrison, KB5WZI

Actually there are good uses for it besides using it for a planter. A
friend of mine K7PF modified one to use with a 2.4G wireless netowrk.
The primary modification was to the antenna feed. he used a tin can fed
about two inches from the end and mounted it with a hose clamp to the
LNB arm
The initial tests were very good with about 20-25 db of gain realized.

Vic wrote:
"What do you think the culprit is now?"

The vertical bar depends on fairly weak desired signals and worsens at lower frequencies.

R-F interference generated within the set is the likely cause. The most powerful harmonic generator is the horizontal output / sweep citrcuit.

This would be an intolerable design defect, so it`s likely caused by a circuit failure. A bad part.

I wouldn`t advise you to cover the set with aluminum foil and super-shield all the antenna parts within the set. Just replace the bad part.

Best regards, Richard Harrison, KB5WZI

See http://www.aesham.com/pdf/096-103.pdf, the RD-78 or RD-98 may be what you are looking for. If you really want to build something you probably want a 1/4 wave of wire, you can coil it a bit to make things shorter overall. To be resonant the antenna should be 1/4 wavelength. 1/2 wavelength antennas have higher gain and need less of a counterpoise (which ends up being you for an HT), but they have very high impedance and need a matching network. 5/8 antennas have better gain but are not resonant and require a bit of a matching network. The 5/8 require a better counterpoise. Longer than 5/8 wave results in more signal going up in the air rather than to the horizon, and even half waves at this frequency are a bit unwieldy for an HT.

I have made 1/4 and 5/8 wave mobile antennas from thin fiberglass tubing running the wire up the center, but these are pretty stiff. For an HT I would just stick with commercial units. You can often pick these up for $5 or so at hamfests. A 2M rubber duck would probably be an adequate match, if not you could snip small lengths off the end.

An antenna that improves your reception will also improve your transmission.

>
Hmm, not at all sure I would agree with that statement. The
license manuals had questions that were ~represenative~ of those
on
the tests, not the exact questions (same for the answers). I
can't
swear to that for the 'Extra', but I do know it to be true for
the
rest of the license class manuals.
I do think that the 'new' tests and testing procedures are
easier
than the older kind which had to be taken in front of an FCC
examiner.
Back then, there was no 'one source' to find all the information
you
needed to pass a test. There was also the intimidation factor of
that
little green room, the too small desks, and that burr-headed,
bow-tied,
be-specticaled examiner watching you from the front of the room.
Now,
there is a 'one source' place to find the questions and answers,
and
if you really want to know what they're asking, it's much easier
to find
out. Personally, the intimidation factor had more to do with how
well
I did on a test than knowing the information required.
As far as the integrity in testing, well, there were
'exceptions'

even under the FCC's testing. How many people do you know of who
ever
tested for a 3rd Class R.O. Permit with a 'Radar' endorsement?
And,
had the 'Permit' stamped with a 'Radar' endorsement?? There may
have
been more, but I only know of one. (LOL)

Warning: This is long, but I think no longer than necessary to describe what I found. If you don't like mathematics, skip this and read the next post after mine.

I thought about the very same question -- whether minimum SWR and resonance are the same thing -- many years ago, long before things like MATLAB and Maple and Mathematica were available, and got nowhere since the mathematics involved is an algebraic mess. I have a copy of Maple V Release 4, which is ancient history but was the current version when I retired from Simon Fraser University nearly 5 years ago; retired faculty can keep the site-licenced versions they had at retirement, but cannot get upgrades unless they pay for them themselves, and my retirement income isn't *that* large. The old version works, and does what I need.

I did a little bit of work with Maple tonight and Maple agrees that it's algebraically a mess. Here's how I set it up. Note that I normalized resistance and reactance variables to the transmission line impedance.

```
SWR:=
(abs(1+A+B*f+I*C*f)+abs(1-A-B*f-I*C*f))/(abs(1+A+B*f+I*C*f)-abs(1-A-B*f-I*C*f))
```

Here the parameter A is the normalized resistance (i.e., R/R_0) at the frequency of zero reactance. For example A would be 0.5 for 25 ohms if the transmission line impedance is 50 ohms. The variable f is the displacement from the frequency of zero reactance; it can be negative or positive, and is zero at the frequency of zero reactance. The parameter B can be negative or positive, and represents the rate of change of the real (i.e. resistive) part of the normalized impedance with respect to frequency; I am assuming that near the frequency of zero reactance, the resistive component changes (if at all) linearly with respect to frequency. Likewise C represents the rate of change of the reactive part of the normalized impedance with respect to frequency, and again I am assuming that the reactive component changes linearly with respect to frequency. In the event that the impedance goes capacitive above the frequency of zero reactance, and inductive below it, you have to take C to be negative; this happens for example at the centre of a full-wave dipole. Upper case I is what Maple demands one use for the square root of -1; my preference as a mathematician is lower case i, and electrical engineers use j. With this interpretation the formula for SWR is equivalent to the usual one.

The obvious thing to do is to differentiate SWR with respect to f, set the derivative equal to zero, and solve for f. Maple chokes when asked to do this, as I did many years ago, before Maple.

So I took some numerical values for A, B, and C and asked Maple to plot SWR for values of f near zero. What I found was interesting.

If I took A = 1 (in other words, at the frequency of zero reactance, the impedance is equal to the transmission line impedance and of course the SWR is 1), but took non-zero values for one or both of B and C, in the neighbourhood of f = 0 the graph showed an SWR of 1 at f = 0 as expected, and this was the minimum. Of course this is to be expected; you can't do better than perfection.

For the case where A = 1, the "curve" wasn't curved; there was a cusp at f = 0, as one would expect with absolute value functions. The derivative, in addition to being an algebraic mess, isn't zero at f = 0 in this case; it doesn't exist there, because of the cusp. For the cases where A > 1, or A < 1, the curve was curved, not cuspy, and the derivative would exist and be zero at the point where SWR is minimized. But as I indicated, setting the derivative equal to zero isn't the way to handle the question; life is too short.

If I took a value of A slightly greater than 1 (in other words, at the frequency of zero reactance, the impedance is real and greater than the transmission line impedance and the SWR is A), and took positive values for B, then whether or not C = 0, in the neighborhood of f = 0 the SWR was

not minimized right at f = 0 but the minimum occurred at a lower frequency; the decrease in resistance with decreasing frequency more than made up for the increase in reactance (when C was nonzero), when the initial resistance at the frequency of zero reactance was too large. Of course if I moved far enough to the left of f = 0, the increasing reactance (if C was nonzero) eventually made the SWR curve move upward again. When you think about it, this really isn't surprising. If instead I took negative values for B, exactly what you would expect happened -- the frequency of minimum SWR was somewhat to the right of f = 0. Again, for a while, when the initial resistance was too high at f = 0, moving in the direction in which resistance decreased overcame the damage done by increasing reactance. By playing with the numerical values of A, B, and C I could change the shape of the curve and the location of the frequency of minimum SWR, but for *all* the numerical choices I used (with A > 1), the same pattern always held, whether C = 0 or not. To get minimum SWR, one has to move away from f = 0 in the direction that brings the real part of the impedance closer to the transmission line impedance, but one should not move too far, or the reactance change will have its say and the SWR will go up again.

If I took a value of A slightly less than 1 (in other words, at the frequency of zero reactance, the impedance is real and smaller than the transmission line impedance and the SWR is 1/A), exactly the opposite happened. To minimize the SWR, one has to move in whichever direction increases the resistance, higher frequencies for B > 0 and lower for B < 0, and for a while this is more important than the increase of reactance from zero, but if you go far enough, eventually the reactance change becomes more important and the curve turns the other way.

If you have one of these programs, try it out. Play with reasonable, and not so reasonable, values for A, B, and C. You may have to choose the negative and positive bounds for f, for your plot, to be numerically quite small to see what is going on, if the minimum SWR frequency is very near, but not at, f = 0. If you confirm what I found (and even more important, if your plots *don't* confirm what I found!), let us hear about it. If you do find a contradictory result to mine, please let me know what the parameters are that produced it. I only tried a handful of numerical examples, and there are infinitely many more out there -- maybe some of them behave differently.

Now if there is no transmission line and one measures the SWR right at the antenna (please, Reg, don't remind me that there is nowhere for the standing wave to stand!) then it is reasonable to expect the resistive component of the antenna impedance to change with frequency in the neighbourhood of the resonant frequency, although I would imagine that for an antenna fed at a current maximum point the rate of change of resistance with respect to frequency would be numerically quite small. What happens in a case like Cecil's, where there *is* a transmission line, is more complicated -- you have to think about the Smith chart.

I'm convinced now that minimum SWR and "resonance" are not necessarily the same thing. Whether it matters, is another question.

David, ex-W8EZE, and retired pure mathematician (despite the use of Maple)

761. Re: A whole new 'back to basics' topic - Monopole fundamentals

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-10 08:25:21 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <3D2BEF71.4000204@eznec.com>
Source record: 139001

To answer the original question, this isn't really news.

A ground plane antenna with horizontal radials has very little radiation from the radials compared to the vertical portion, so for practical purposes it's a monopole. The gain of a ground plane antenna in free space is nearly identical to the gain of a vertical dipole in free space.

The "gain" difference between the monopole and dipole in Logan and Rockway's analysis is due simply to the different environments they're measured in. The dipole is in free space. The monopole is in a half-space, with the other half being the ground plane. So the energy from the monopole is concentrated in half the volume that the dipole energy is. ANY antenna measured over an infinite ground plane will have twice the field strength (or 3 dB greater gain compared to any single reference antenna) as the counterpart antenna measured in free space. And a dipole over ground has considerable gain relative to a dipole in free space. The amount depends on the dipole's orientation and the direction in which it's measured.

There's nothing wrong with the NEC and MININEC analysis that gives these results. Any other conclusion would be wrong.

Thanks Roy, I was hoping to hear from you...

How about the other report conclusions, do you have any comments about those
?

...2) The effective area of a receive monopole is one-fourth that of a
dipole.
...3) If the monopole and dipole are in identical fields, then the dipole
will deliver to a matched load four times the power.

Number 2) above was presented in the report as being "news".

At no point did I say that the tuner would make a non resonant antenna resonant...
I know what the tuner does, it makes the radio think it is a good match (impedence wise).
And I am aware that a resonant antenna may not always have the best impedence.

David or Joe,

If you would like to vary frequency and monitor SWR, simultaneously checking line input impedance for zero reactance, download program DIPOLE3 which models the situation.

The reason the line input reactance is not EXACTLY zero at minimum SWR is because the radiation resistance also changes a moderate amount with frequency.

Another minor reason is that Zo is not a pure resistance. It is R+jX.

Source record: 139011

It is a fundamental property of LCR tuned circuits of reasonable Q, say 5 or greater, that as the impedance magnitude versus frequency passes through a minimum or a maximum, the reactance passes through zero. L,C & R are assumed to be linear and independent of frequency.

If loss in C is equal to loss in L then the foregoing is true for any value of Q.

In the case of antennas, minimum SWR does not occur EXACTLY when line input reactance is EXACTLY zero simply because the radiation resistance varies rather slowly with frequency. It breaks the rules.

The variation of SWR due to a changing radiation resistance is superimposed on the resonance curve. It puts a slope on it. Which causes the minimum to be offset.

But considering the accuracy of so-called SWR meters, for practical purposes SWR = minimum when X=0.

Radio amateurs are inclined to suffer from delusions of accuracy !

Reg, G4FGQ

That seems reasonable - if you look at it in Smith chart terms, it means that the impedance-frequency plot is making a swing past the center, then curling round and cutting through the X=0 axis. It comes closest to the center at (42+j8) which you therefore measure as minimum SWR; but the place where it cuts the X=0 axis is farther away from the center so the SWR is higher.

"Resonant frequency" usually means when X=0. It's not strictly correct to use the term to mean the frequency where SWR is a minimum, because those two frequencies don't have to be the same - and generally speaking they are *not*.

The main cause of confusion is the "half-wave" center-fed dipole, where the resonant frequency and the dip in SWR very nearly *are* the same. That is because the resistive part of the feedpoint impedance is changing much more slowly with frequency than the reactive part, so the reactance dominates the SWR, and the SWR minimum is very close to X=0.

But in spite of being very common, the "half-wave" dipole is actually a special case. Cecil's antenna/feedline system is a better example of the way things can be.

Well, the formula for an SWR referenced to 50 ohms based only on impedances is well known. We don't even need the SWR meter. We can calculate the 50 ohm SWR based only on the impedances involved.

The point is: If the MFJ-259B is correct in the measurement of the following impedances, then minimum 50 ohm SWR doesn't occur at resonance for my antenna system used on 40m.

7.015 MHz, impedance measured at 21+j0, calculated 50 ohm SWR = 2.4:1

7.120 MHz, impedance measured at 42+j8, calculated 50 ohm SWR = 1.3:1

Incidentally, the measured common mode current is minimum at the 21+j0 point not at the minimum 50 ohm SWR point.

>Is this Common or Differential Mode?

Across would be between the two or more conductor transmission line,
or the differential mode.

As you should plainly see by the example I gave, termination impedance
does not necessarily or even often define the common mode excitation
of the system.

Richard Harrison provided an excellent demonstration of how thinking
the two are tied directly together by Ohm's law and power equations
trips people up.

The autotransformer, while intentionally added to a Reflection
Beverage, occurs naturally without lumped components in most systems
to varying degrees.

This is why baluns like W2DU style baluns can work quite well in some
50 ohm systems (with low SWR), and burn up at very low power in other
50 ohm systems.

Small ground system verticals can be problematic for common mode, as
can any antenna where the feedline does not exit at a "neutral" point
in the induction fields surrounding the antenna. The EH antenna is a
prime example of how to excite the feedline with extreme common mode
excitation voltage levels, even though the "across" (differential)
voltage of the antenna feedpoint is very low.

If you do not see lowest SWR at resonance, your meter or method is in
error.

Dan is right, lowest SWR always occurs at resonace.

If you do not see lowest SWR at resonance, your meter or method is in
error.

Dan is right, lowest SWR always occurs at resonace.

Of course, this only applies to high-Q systems being discussed. I
forget sometimes the thread police are lurking.

I could design a system where the slope of reactance change is much
less than the slope of resistance change, and then lowest SWR would
not necessarily be resonance.

Hi all,
here in Germany, a commercially made OCF dipole named FD4 has been on the
market for more than 25 years. It covers 80/40/20/10 mtrs and the idea to
extend it to 15 mtrs by adding a second OCF dipole at the feedpoint was
promoted by a DJ2 (I guess suffix was EY but not sure) in the mid
seventies. There are two more articles in cq DL magazine (one in '83 and
one in '84) by DL1BBC et al that cover the idea to double the length of
the 15 mtrs OCF in order to cover 30 mtrs as well. I turned out that the

antenna is resonant with good swr on 17 and 12 mtrs as well. The '84 article covers doubling the length of the original 41.5 mtrs FD4 part in order to add 160 mtrs as well.

If you model the FD4 with the 30/15 mtrs OCF added, you discover that the approx 10 mtr long part of the added OCF is quarter wave resonant on 40 mtrs and the 5 mtrs long part is approx resonant on 20 mtrs, so that the current distribution will change from the original FD4. What I found when trying this idea (with antenna in the attic in a kind of loop) was that my 20 mtrs resonance moved down to less than 13.5 MHz, but SWR on 20 wasn't above 2.0. All resonance are broad, so this effect isn't important (actually it is seen in the graphs in the cqDL article, but the antenna described there is only 8 mtrs above ground and even closer to a nearby roof).

There are two versions of the FD4 on the market which differ slightly in length (41.5 vs 40.7 mtrs) and in power rating (500 vs 2kW PA input). The high power version uses what they call a duplex balun. It symmetrizes in one step and transforms 1:6 in a second step, while the old balun in the 500 W version is a voltage transformer and was said to be responsible for TVI due to current on the outer conductor of the coax.

But, seriously, I know that you can make a noninductive/nonreactive
resistor out of a Moebius loop, attaching the leads opposite each
other on the loop. If I remember right, it won't couple to metal,
itself or other fields. I wonder how well it would radiate. Or, more
importantly, how small it could be for working 160m. Theoretically,
you can bunch it up in a ball and it will work the same, so...

Hi Richard,

I have the ARA 60 (there's no 'S' version in Germany) and am satisfied with that antenna. The version I have is called old version, it looks like PVC rod of about 7 cm diameter, the newer version looks like a whip.

I can use the antenna from less than 50 kHz to more than 146 MHz (heard OSCAR 10 with it on a ICOM R7000 RX).

I don't have any problems with 3rd order intermod (on a AOR 7030) but have little problems with 2nd order intermod (local am bc mixes with 6 MHz bc stns and produces some spurs near 40 mtrs and a lot of am bc stns appear again between 2 and 3 MHz).

Some other problems I had could be traced back to an impure local oscillator in the AOR 7030. The antenna can produce so much voltage that using a simple preselector is a good idea (at least here in central europe) even if you use a receiver with a high IP like the 7030 if you want full sensitivity, but cou can also reduce the overall gain if needed.

I live in a village 20 km west of Hannover, although I have railway only 200 mtrs away, the location is very quiet and I can always hear external noise (or better weak stations in the noise) with my ARA 60, so that you should not be limited by the antenna's noisefigure.

I'm gonna have to disagree with you again, Tom. Methinks my
antenna system is again a thorn in the side of your "always". :-)

Which of the following impedances results in the lowest 50
ohm SWR?

21+j0 at 7.015 MHz or 42+j8 at 7.120 MHz.

Those are measured values from my antenna system when only the
frequency is changed. Any system, where resistance is changing
toward 50 ohms faster than the reactance is changing, can exhibit
this characteristic. Please see Ian's posting.

>IS CHEAP.
>This stuff is always fun. Nature contains exquisite beauty.

I just did this and you were correct. It was surprising and fun.

My 2d floor wiring in the ceiling (where the smoke detector lives) is
RF hot. The field is also strong near the duct and flues in the
vicinity of the antenna (i.e. 10-20 ft away), but diminishes quickly
with distance. Either the steel is merely concentrating the signal or
it is dissipating rapidly in eddy currents. The steel is not pumping
much RF into the house wiring.

OTOH, the hottest items were the electrical wires in the attic framing
near the antenna (and roughly parallel to the antenna leg it was
near). These are the most likely source of the RF getting to the
smoke detectors.

So, I appear to have what must be a typical problem for anyone who
has his dipole attached to his house: common mode RF picked up by
house wiring near the antenna.

Any suggestions of where I should start my research into solving this
will be appreciated.

How's that? All the the popular 5/8-wave antennas have a matching unit (normally a coil in the base) which adds the necessary inductance so that resonance is obtained at the desired frequency the result is the same - lowest VSWR point.

OK. What that means is the separate transmit and receive *systems*
aren't reciprocal unless identically well matched to the antenna.

Richard Clark wrote:
"Look at the introduction---
it is the effective area that resolves the 6-dB discrepancy between
measurements and analysis."

Effective area doesn`t give the authors any slack if they stick to
"capture area".

Capture area is a definition which squares with power per unit area in a
wave. It is a definition based on that. Its value is: Gain times
Wavelength squared divided by 4 pi.

Terman gives an example: Gain of the elementary doublet is 1.5.
Therefore, its capture area is 0.12 times the wavelength squared.

Best regards, Richard Harrison, KB5WZI

Tom, W8JI wrote:
'Richard Harrison provided an excellent example of how thinking the two are tied directly together by Ohm`s law and power equations trips people up."

Your receiving antenna is tied to the transmitting antenna by Ohm`s law.

The current in the transmitting antenna determines the voltage in your receiving antenna. This application of Ohm`s law is called "mutual impedance". Double the transmitting antenna current and you double the receiving antenna voltage becauset the Ohm`s law impedance (coupling) does not change. It is fixed by the situation and conditions of the antennas.

In a practical situation of amps in the transmitting antenna, and resulting millivolts in the receiving antenna, the ratio of volts to amps, the Ohm`s law mutual impedance, is very small indeed. There is little coupling, but there is some if you are receiving a signal.

Best regards, Richard Harrison, KB5WZI

Doc is correct. the G5RV uses the twin lead as a transmission line transformer, and/or matching device, and needs to be run perpendicular to the antenna itself. And the fact remains, it doesn't work well if the antenna is in an inverted V configuration. If you use twin lead (ladder line) to a doublet, then any losses you have as a result of VSWR isn't of much concern. The major loss will be in the internal balun, and if it is of the correct type, the losses are too great under most amateur operating conditions. A better solution would be to use a doublet long enough to cover 80 and use it for the rest of the bands as well. One problem you'll no doubt encounter is the length is just right (or just wrong depending upon your view) is trying to feed the double at or near a voltage node—high impedance. You have two solutions. Use more than one doublet pair, or very carefully select the length.

One pair of my doublet is resonant at 6.9 Mhz, and the other at 15.6 Mhz. This antenna works well on all bands from 40 thru 10, and will tune satisfactorly on 30, someting the G5RV doesn't do well.

The latest issue of QST has a very good article on wire antennas written by Hal Kennedy, N4GG. It bears reading.

It's probably a reflection caused by some component inside the TV which has been unmasked by the weak signal going to the TV. You didn't say what kind, model etc., but it really doesn't make much difference. The "FIX" probably isn't worth the cost, and maybe it's time you invested in a good digital TV. In any case, it is a darn good excuse for one, isn't it?

Hi Grant,

Follow this link:

http://groups.google.com/groups?threadm=b6b4e772.0202010017.32110d46%40posting.google.com

and look at my answer to Jason. I have used this antenna with my TH-D7
and I am using it now on an IC-R2 scanner. It performs much better
than the supplied rubber whips and when you are done you can roll it
and put it in a pocket.

Just try it, it is cheap and easy to make.

Toni

795. Will paralleled dipoles have smaller Bandwidths?

798. Smith Chart Tutorial

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-10 15:56:02 UTC
From: Dick Carroll <dixie@townsqr.com>
Message-ID: <aghleirln0@208.207.71.153>
Source record: 138940

Cecil, maybe this is a good spot to start with the thread on the Smith Chart.

I finally found a plain language explanation of the Smith Chart and how to use it, in my own library, in a book entitled "Amateur Radio-Theory and Practice" by Robert L Shrader, W6BNB. I found the book at a hamfest a couple years ago and had loaned it out to a new ham who recently returned it. I recalled that in leafing through it initially I had noticed a Smith chart, and last night I went back to see what treatment Bob had given the subject. Characteristically, it was exactly the treatment that is needed to learn to use the chart initially. In 4 fairly short paragraphs Bob conveys exactly what is needed without all the usual disorienting chaff. It uses an example chart which one can make up with the downloaded chart from

The book is 20 years old and evidently long out of print. I imagine I could quote those 4 paragraphs here with proper credit, for others to learn also. It will be without the Smith Chart graphic, but one can easily make up your own with the instructions given. If you happen across a copy as I did it's worth grabbing. Bob's major work, "Electronic Communication", ISBN 0-07-057150-3, is a classic in the field and covers almost anything connected with radio that you can name,(at least in that time, but it's also 20 years old) but contains nothing on the Smith chart. I wish he could update both of these volumes but it seems doubtful.

BTW, I worked Bob on 20 meter CW a couple months ago while portable visiting my daughter in the Salt Lake City area. He's in his 80's and still makes that cootie key hum!

Here goes.....

From "Amateur Radio Theory and Practice", by Robert L. Shrader, W6BNB, ISBN 0-07-057146-5 Gregg Division, McGraw-Hill Book Company, 1982, page 198:
Quoting;

A Smith Chart can be used to make many computations of antenna and feed-line mismatches, SWR, etc. The horizontal line across the chart represents the "resistance component". The center of the chart, the "1.0" point, is where things start. For example, if you know that a 50ohm transmission line is terminated with a resonant 150ohm antenna, the SWR must be 150/50, or 3:1. By using a pencil-compass and drawing a circle from the chart center through the "3" on the resistance line, you will have a circle that tells you all the ratios of Zo (transmission

line impedance) to Zl (antenna impedance) of nonresonant antennas that will give a 3:1 SWR. If you move 180 degrees around the circle, you find that the resistance line is again crossed at the 0.33 point. A 1:0.33 ratio is the same as a 3:1 ratio.

The curves above the R line, and originating at the right end, are labeled "inductive reactance component" (Xc curves are below). The 3:1 SWR circle tells you all the ratios of R + jX (Sec 4-9)(in the book) that a nonresonant antenna might have which would produce a 3:1 SWR reading on the SWR meter. For example, the 3:1 circle happens to cross both the R = 0.5 (Zo) circle and the Xl = 0.65 curve. This means that if you coupled the output of a 50 ohm transmission line to the feedpoint of an antenna that had a measured impedance of R + Jx or R = 0.5 (50 ohms) or 25 ohms, and an Xl = 0.65 (50 ohms), or 32.5 ohms, the SWR meter in the feedline would read 3:1. At all other places where the R circle, the X curves and the 3:1 circle intersect, a 3:1 SWR would result.

The R + jX values of a dipole having an unknown feedpoint impedance can be measured with an R-X meter. Such a meter consists of an RF oscillator and a calibrated impedance bridge. The transmission line is removed from the antenna, and the R-X meter is connected to the antenna feed point. The meter is tuned to the operating frequency and the controls varied to a null indication of the bridge. The settings of the dials on the meter now indicate the values of R and X that are exhibited by the antenna at its feed point.

Suppose a 50ohm transmission line output is coupled to a dipole with a measured feedpoint impedance of R + jX = 75 +j 100. *Normalizing* the R part of the R + jX value by *dividing by the transmission line impedance* gives R = 75/50, or 1.5. Normalizing the +jX value gives Xl = 100/50, or 2. The normalized R + jX is therefore 1.5 + j2. A circle with its center at the chart center and passing through the R = 1.5 and the + jX = 2 curves on the chart will indicate the SWR that will result when the feedline is coupled to the antenna. (What SWR do you find it to be?) How to correct this antenna to make it present a 1:1 match to the feedline can also be determined by a Smith chart, as can be the return losses, power reflection coeficient, voltage or current reflection coefficient, attenuation, reflection loss, peak of standing waves, and power transmission coefficiet.

(end of quoted material)

While not a comprehensive tutorial, this is certainly enough to get one familiar with the Chart so that one can learn more from there.

And there's plenty of room for further discussion here :-)

And it might set some hams to searching for Bobs's book. I once saw it for sale in one of the online used book stores.

> and a receiver connected to those antennas.

In the paper I forwarded, the proof of reciprocity utilized a source
and load but
it certainly is not required for a reciprocal relationship to exist
between two ports.

Reciprocity between two ports in a network exists when the transfer
impedance, or admittance, is the same in one direction as in the
other. In other words, Zji = Zij or Yji = Yij. That's all there
is to it. In the usual matrix representation, reciprocal networks
have Z, Y, or S parameters which are symmetrical about the diagonal.

The transfer impedance between two ports (port 1 input, and port 2
output) is defined as the voltage applied to port 1 divided by the
short circuit current in port 2 with all other ports open circuited.

Various other equivalent relationships exist, such as the
representation used in scattering (S) parameters, and for the very
special, but unnecessary, case where a conjugate match exists
somewhere in the system. They all can be reduced to the basic
definition given above with algebraic manipulation. Any good network
theory textbook will provide the proofs.

Actually, my memory was fuzzy on exactly what reciprocity means. It
means in (almost) any RF communications system, if the receiver and
transmitter positions are swapped, the result will be the same.

Cross-posted to: rec.radio.amateur.antenna,misc.consumers.house,rec.video,sci.electronics.repair

Highly sensitive televisions can show these symptons. The television is simply picking up its own radiated energy.

These problems are sometimes worse when internal aerials are utilised even loft based aerials.

Problems are also usually exagerated when the television is placed into the corner of the room. Withdrawing the tv from the corner even a few inchs / cm can make big differences.

The placement of cables and aerial interconnection leads at the rear of all the electrical equipment can have dramatic effects. Cooling up some leads and altering there position in relation to other leads again can give big improvement.

Adding ferrite cores to leads can also reduce cross interference.

Right.

> Another minor reason is that Zo is not a pure resistance. It is R+jX.

Also right, but at reasonable frequencies and with reasonable coax, X is
numerically small compared to R.

> system used on 40m.
>
> 7.015 MHz, impedance measured at 21+j0, calculated 50 ohm SWR = 2.4:1

The normalized resistance at resonance is
A = 21/50 = 0.42.

> 7.120 MHz, impedance measured at 42+j8, calculated 50 ohm SWR = 1.3:1

The rate of change of resistance with respect to frequency is
(42 - 21)/(7.120 - 7.015) = 200 ohm/MHz.
This normalizes to
B = 200/50 = 4 (MHz)^(-1).
The rate of change of reactance with respect to frequency is
(8 - 0)/(7.120 - 7.015) = 76.2 ohm/MHz.
This normalizes to
C = 76.2/50 = 1.52 (MHz)^(-1).

I am using the notation of my earlier posting
<ryeburn-1007020011150001@bni030qny8kc.bc.hsia.telus.net>.

I used these values of A, B, and C and asked Maple for a plot. Here f = 0
at 7.015 MHz, with this offset frequency value also measured in MHz.
Reading from the Maple graph, the SWR values at various frequencies across
the 40 metre band are as follows (use a monospaced font):

f Freq SWR

-0.015 7.000 2.78
0.000 7.015 2.38 (Resonance)
0.105 7.120 1.28 (Cecil's measured frequency of minimum SWR)
0.130 7.145 1.24 (calculated minimum SWR)
0.285 7.300 1.75

The 25 kHz discrepancy between Cecil's measured frequency of minimum SWR and my calculated frequency of minimum SWR is easily explained if the measured resistance and reactance figures he gives are slightly in error, or if his SWR measurements are slightly in error, or if (contrary to the simplifying assumption of my calculations) R and/or X are not linear functions of frequency in the neighbourhood of resonance. The SWR curve is nearly horizontal near its minimum, and anyway what's a frequency difference of 25 kHz and an SWR value difference of 0.04 among friends?

Resonance and minimum SWR differ here by 130 kHz, and I can't say "What's a difference of 130 kHZ among friends?". Also in this example, the SWR curve is broader on the high frequency side of the frequency of minimum SWR. The 1.75 value for SWR observed at 7.300 MHz (0.155 MHz above the frequency of minimum SWR) occurs again at 7.055 MHz (only 0.90 MHz below the frequency of minimum SWR). This is rather unsymmetrical. Maybe that's why, in the old days, the CW sub-bands were lower in frequency than the phone sub-bands ;-)!

You don't need steeper resistance curves than reactance curves for this to happen.

I took the values A = 0.42, B = 4, C = 1.52 calculated from Cecil's data for the 40 metre band (used in an earlier posting of mine) and increased C by a factor of 10, to C = 15.2. Here's what Maple shows:

f Freq SWR

-0.015 7.000 3.0
0.000 7.015 2.4 (Resonance)
0.015 7.030 1.25 (Minimum SWR)
0.285 7.300 14.75

I think you'll agree that this is a much more narrow band antenna than the typical 40 metre dipole. At least I never had one that bad back in my days as W8EZE. Of course I never used tiny antennas with loading, such as are required for mobile use. Yet even with such a high Q, there is still a 15 kHz difference between resonance and minimum SWR frequency. The difference in SWRs (2.4 versus 1.25) is about the same as in Cecil's case (2.38 versus 1.24). The calculated frequency difference, 15 kHz, is an order of

magnitude less than the calculated difference for Cecil's antenna (130 kHz), and that's not surprising with C now an order of magnitude higher than before.

It seems that the ratio of C to B is what counts -- the higher it is, the closer to resonance the minimum SWR frequency will be, but I have yet to see a numerical example where they are the *same* except for the case where A = 1 (i.e., the resistive component of the impedance, at resonance, is equal to the transmission line impedance, resulting in an SWR of 1.0 at resonance).

With broad-banded antennas (e.g. those with large effective conductor diameter such as can be obtained by using multiple equal-length wires fanned out a bit on each side of the centre of the dipole), where C/B will be numerically small, the discrepancy between resonance and minimum SWR could be significant compared to the width of an amateur band, perhaps even more extreme than Cecil's antenna exhibits.

810. Re: Matching coil vs antenna length - mobile antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-10 19:37:47 UTC
From: k7itm@aol.com
Message-ID: <3200347.0207101137.260e9838@posting.google.com>
Source record: 138950

Resonance of what? The antenna structure proper as measured at the feedpoint, or the whole system including matching networks and transmission lines? VSWR measured where? At the point where we connect the transmitter to the feedline, or at the feedpoint of the antenna proper?

I think it's valuable to realize that efficient radiation does not require resonance of the antenna element(s), and the feedpoint impedance may be much different from the desired transmitter load impedance (presumably the reference impedance for our vswr measurements). If we measure vswr at the feedline input, and include whatever matching networks are in the system, it's certainly not generally true that lowest vswr occurs at a frequency where the reactance is zero (one possible definition of "resonance"). Cecil gave one example, and there are lots of others.

But I think the vswr versus frequency is a red herring. Design the antenna to have the radiation pattern you want, and a feedpoint impedance you can deal with over the frequency range of interest, and then design the coupling to that feedpoint impedance and the decoupling of the feedline from the antenna fields. There's no need to assume anything has to be "resonant," though that may be convenient in some cases.

Cheers,
Tom

Well, if it won't couple to conductors or fields, it sounds to me like
it won't radiate very well. :-)

> 0.285 7.300 1.75

David, if you've ever used an MFJ-259B, you probably know one gets
what one pays for. With that in mind, I ran the above measurements
and obtained the following for my one wavelength ladder-line fed
dipole on 40m:

6.900 MHz 13+j0 SWR = 3.8:1
7.000 MHz 18+j0 SWR = 2.8:1
7.025 MHz 21+j0 SWR = 2.4:1
7.050 MHz 24-j4 SWR = 2.1:1
7.075 MHz 29-j5 SWR = 1.7:1
7.100 MHz 35-j7 SWR = 1.5:1
7.125 MHz 42-j8 SWR = 1.3:1
7.150 MHz 50-j10 SWR = 1.2:1
7.175 MHz 60-j12 SWR = 1.3:1
7.200 MHz 74-j15 SWR = 1.6:1

Even given the inaccuracies involved, the overall trend seems to be
consistent and obvious. The resonant point is 250 kHz away from the
point of least (50 ohm) SWR. Because of the A/D resolution involved,
the above impedances of 18+j0 and 21+j0 probably should have been 18+j1
and 21+j3.

Seems every time I make measurements on my antenna system, I seem to encounter
things that disagree with conventional amateur radio wisdom which makes me
wonder if conventional amateur radio wisdom is suffering from a case of arrested
development.

Tom, are you giving us conventional wisdom here or are you going against
conventional wisdom?

I have a one wavelength dipole on 40m fed by 3/4WL of ladder-line. The
difference between the "resonant" frequency and the minimun 50 ohm SWR
frequency seems to be about 250 kHz. Does that fly in the face of
conventional wisdom or agree with it?

the 'common mode' is there even at a 90 degree feed angle, just its
excitation is reduced to near zero by being symetric with respect to the
fields generated by the dipole.

> Best regards, Richard Harrison, KB5WZI

true, and in this particular set of conditions that calculated percentage
will work. however, change the angle to 44 degrees from 45 and the

percentage will change. change the frequency and the percentage will change. change the height above ground and the percentage will change. so yes, you can measure it for one set of operating conditions and determine some value that may be useful for that set of conditions... but you can not generalize that value, or even make predictions about how it changes with varying conditions. about the only thing that probably holds in most cases is that the percentage calculated holds over some reasonable range of power input to the dipole. but that is the only valid relationship between the common mode voltage and the differential voltage. there is no requirement that the common mode voltage be smaller than the differential voltage since the impedance of it's path may be much larger than the differential mode impedance. and there is no generalized formula you can use to compare the two of them as they depend on different characteristics of the system.

this may be 'basic' but that does not mean it is 'simple' or obeys a single law like ohm's or kirchoff's. volumes have been written on calculating impedances and propagation velocities of the many propagation modes on transmission lines, in wave guides, and even on high voltage power lines.

Hi Richards,

Can either of you explain what these authors are up to with their "effective area". I had assumed that they were talking about something closely 'related' :-) to Capture Area. Whatever it is that they are talking about, it is divided by 4 (!) for the monopole*; and the monopole* has +3dB more (!) gain.

Thanks.

Thanks very much for the analysis. I went through this exercise
(although manually) several years ago and came to the same conclusion.
And once in a while I encounter a model with EZNEC that illustrates it.
In practice, the points of resonance and minimum SWR are nearly always,
but not always, so close as to seem like the same frequency.

The following is from "Networks and
Systems" by D. Roy Choudhury:
" If we consider two loops A and B of a
network N and if an ideal voltage source
E in loop A produces a current I in loop
B, then interchanging positions, if an
identical source in loop B produces the
same current I in loop A, the network is
said to be reciprocal.
" The dual is also true.
" A linear network is said to be reciprocal
or bilateral if it remains invariant due to the
interchange of position of cause and effect
in the network."
Later, "A reciprocal network is comprised of linear, time-invariant,
bilateral, passive elements." (This isn't
exactly what he said; I changed it slightly
to correct his language.)
I don't know how the above relates
exactly to antennas. The real-world
atmosphere certainly isn't time-invariant,

but I don't suppose that will stop those who like to use the simplifications of network theory to explain all electrical phenomena.

> ...2) The effective area of a receive monopole is one-fourth that of a
> dipole.

If an antenna is 100% efficient (a reasonable approximation for the discussion at hand), the effective aperture (or, as hams like to call it, "capture area") is exactly proportional to gain. So the effective aperture of a monopole over ground is exactly twice as large as for a dipole in free space. The effective aperture of a dipole over ground is considerably larger than for a dipole in free space (the amount depending on orientation and direction in which the aperture is measured), and the effective aperture of a ground plane antenna (essentially a monopole) in free space is very nearly the same as for a dipole in free space.

In their paper, Logan and Rockway claim that the monopole over ground has four times the effective area of the dipole in free space, and use their equation 18 as justification. Their equation 18 relates power received, power transmitted, and gains, and shows that the ratio of power received to power transmitted would be four times as great in a system of two monopoles over ground compared to two dipoles in free space. However, you can clearly see from their equation 17 and the gain figures they give that the effective aperture of the monopole over ground is twice, not four times, the effective aperture of the dipole in free space.

Be aware that the effective aperture is different in each direction,
just like the gain.

> ...3) If the monopole and dipole are in identical fields, then the dipole
> will deliver to a matched load four times the power.

If the monopole over ground is immersed in the same field as a dipole in
free space, the monopole will deliver to a matched load twice the amount
of power as the dipole, since it has twice the effective aperture. But a
ground plane (monopole) in free space will deliver very nearly the same
amount of power as a dipole in free space.

Thanks very much for your review and report. I very much appreciate it.

It is 'news' (as far as I'm concerned) that their paper is apparently *not*
correct. These guys are in a position (writing widely-used NEC programs,
writing papers, advising military and government decision makers) where such
errors could be propagated ad infinitum. It could lead to all sorts of
troubles.

In addition to that, if reciprocity holds, several important results
follow. First of all, the transmitting and receiving patterns of an
antenna are identical. Then, since directivity depends only on the
shape of the power pattern, the directivity of the antenna when
transmitting is the same as its directivity when receiving. If the
terminal impedance of a transmitting antenna is Zt, then the load
impedance required for max power transfer when receiving is the
complex conjugate Zt*. 73,
Bill N3WK

I like the way that you laid that out. Each naturally follows the previous.

The only part that I've yet to understand is why a 'structure' (part of an otherwise ordinary antenna) couldn't be arranged that would distinguish between a *spherical* wavefront being emitted by the transmitting antenna, and a *planer* wavefront arriving at that very same antenna in when in receive mode. I can't think of such a structure, but the wavefront shapes are very different. It 'seems' possible. If such a structure were possible, then one could make a receive-only, or a transmit-only, (non-reciprocal) antenna.

Obviously the burden of proof is on the 'inventor' (sic) to present an example... sigh... Suggestions welcomed.

Just get a thin wire of flexible steel from a model toy shop; they use
it in radio controlled planes and similar. Here they call it piano
wire, because apparently it is similar to the wires used to make
pianos. Well, cut it to about .27 wavelength (don't know why .27
instead of 1/4, but most references I found recommended it). Solder it
to the inner pin of the SMA and put it in place. Fill the inside of
the SMA with two component epoxy or other heavy-duty glue. Put
something at the other end of the wire to prevent it from harming you
or others. You have it. You can bent it, allow rain to fall on it, ...
Most important, if the wire is thin enough it acts as a "mechanical
fuse" for your SMA. It will bent before your SMA breaks.

Just another thing: Cut a 1/4 w. thin wire and put and 'eyelet?' on
it, so that you can put it in the SMA before screwing the antenna on
it. It will kind of work as a radial. It DOES make a difference with
any antenna you are using!

Toni,
Is there a way to post a picture if this antenna on the web? And what is
this radial that you are talking about? What is your formula for both .27
and 1/4 wave? Also, I am using a BNC, but I would guess that it would be
similar?
Thanks, Grant

> dipole.

The usual expression for effective area is G(lambda^2/4pi), but in the
report it's (after moving terms around) given as G(lambda^2/16pi).
I've heard the lambda^2/4pi term described as a "universal constant",
so maybe the authors are trying to mess with Mother Nature in their
attempt to resolve discrepancies between measurements and predictions.

Eqn 30 can also be written as (G/4)(lambda^2/4pi), so their effective
gain for the receiving monopole is -0.83 dBi.

In re-freshing my memory concerning reciprocity, the transmitting and
receiving patterns of an antenna are identical, and the directivity is
the same either when transmitting or receiving. So it would seem that
their conclusion violates reciprocity. 73,

Source record: 138872

I am running sloping loops on 30 and 40 meters, about 50 feet high at the apex (the feed point) and 30 feet high on the two ends. I find them to be good antennas with surprising directivity. I feed each of them directly with coax - a random length of 50 ohm coax, followed by a 1/4 wave 75 ohm coax matching section. With this arrangement the SWR is low and flat; without the 75 ohm matching section I can't get the SWR under about 3:1.

I'm not familiar with this text, but later works (such as Jasik or Johnson) refer to this as the "coupled impedance". The mutual impedance for two elements is defined as follows:

V1 = I1Z11 + I2V12
V2 = I1Z21 + I2Z22

where

V1, V2 are the voltages at antennas 1 and 2
I1, I2 are the currents at antennas 1 and 2
Z11, Z22 are the self impedances of antennas 1 and 2
Z12 = Z21 = the mutual impedance between antennas 1 and 2

V2/I1 = Z12 or Z21 only when I2 = 0, that is, when the second element is open circuited. (See the example on page 263 of Kraus, First Ed., or p. 423 of Kraus, Second Ed.) For other termination conditions, V2/I1, the coupled impedance, isn't equal to Z12 or Z21, the mutual impedance.

The mutual impedance depends only on the physical characteristics of the elements, not to the currents flowing in them. The coupled impedance depends on the currents in the elements and on the mutual impedance.

Who's Poynting ?

Oliver Heaviside has also been forgotten it seems. It was his intellect and self-taught genius which generated the few beautifully simple equations describing electro-magnetic radiation which appear in all the World's engineering textbooks in all languages but are still incorrectly attributed by plagiarists to Maxwell.

Please give credit where credit is due.

>should read: lack ground connection, by design, at the antenna feed?

The only two feeds I know of that are ideal are a perfectly balanced
dipole or closed loop with a perfectly balanced feeder, or a vertical
with an infinite ground systems and the feedline leaving below that
ground.

Even though a small vertical like the Hygain, Cushcrafts, or others
might have "grounds", they are very small poor grounds and the
feedline exits the area at a point where the high electric field
excites the cable. The exciting voltage can be MANY times the voltage
across the feedpoint.

The Reversible (or simple Reflection) Beverage has a ground, but
intentionally initiates this same or similar effect through the use of
an auto-transformer or a conventional transformer with a secondary
that feeds the center tap of a primary that is across the two antenna
wires. The antenna wires can be coaxial or balanced construction.

The EH antenna would be another example of an antenna that
intentionally (or accidentally through oversight by the "designers")
excites the feedline in the same manner as the Reversible (or
Reflection) Beverage and nearly as much as the verticals I mentioned.

I'm sure any engineer who has worked on the vertical antennas, or many
users, have learned about the non-fixed relationship between feedpoint
voltage and voltage exciting the feedline in common mode.

Most antenna systems are between the two extremes of a perfect system,
and a totally out-of-whack system like the EH antenna.

Considering these examples, however, will show us that in all but
perfectly balanced systems or perfectly unbalanced system...and with
perfect systems with feedlines leaving at ideal locations....the
simple idea that you can look at the feedpoint "across" voltage to
determine common mode excitation voltage is flawed.

The range is from "no big error" to cases where there is a phenominal
error. That is why it is best to disuade people from assuming the
"across" voltage is what drives the common mode system. The excitation
does not even need be from the same ultimate source, let alone be
related by simple formula (as Harrison attempted to do).

Thinking the differental system is directly tied in some fixed established relationship to the common mode, such as through power formulas, will be in error many times more often than not.

833. Help? Is there significant signal loss with too many outlets???

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-11 00:59:59 UTC
From: mouln@yahoo.com
Message-ID: <30da9028.0207101659.4a5aac7a@posting.google.com>
Source record: 138876
Cross-posted to: rec.radio.amateur.antenna,rec.video

Just moved to a home that was wired for tv.
There are a total of 7 outlets connected to a TV antenna in the
attic.

Some channels come in strong and some are weaker. I want to avoid a
signal amp
because of the video noise they introduce.

2 of the seven outlets have televisions hooked up via RG6 coax.

I have been reading about cable splitters and and the signal loss they
cause. I am wondering if outlets might be diminishing the signal
arriving at each of the seven outlets.

I have also been told that the unused outlets should have terminators
screwed in to the cable jacks that these devices would help get a
stronger signal at the 2 used outlets.

Would appreciate any info from person knowledgable on antenna systems
and signal loss. Thanks
Jim

But the topic here was a short loaded mobile antenna Ian, not a dipole
or a dipole with a tuned feeder. Sometimes (or almost always) threads
move away from from what was actually asked and responded to.

With a smallish antenna the slope of resistance is gradual, but the
slope of reactance is steep. In that case, resonance is established
within instrument capability as the point of lowest SWR.

If you have a long feedline, especially one with high standing waves
in the system, the (frequency) slope of resistance can be steep
compared to the slope of reactance.

That is why analyzers like the AEA that try to guess the sign of
reactance by observing the increase or decrease in impedance with
frequency make errors in guessing the sign about half the time.

I use a quarter to determine the sign of reactance, heads is inductive
tails is capacitive. It works just as well once an antenna is
involved.

Source record: 138878

I was out of town for a few days, and returned to find a somewhat humorous thread. With "BASICS" in the title, a good deal of the discussion seems to revolve around "depends on what you mean by depends".

Let's get back to basics, and consider the currents on the two wires of a twinlead conductor, call them I1 and I2. Define the positive direction of both currents to be the same, say toward the load.

There are two currents and two currents only. The concept of differential and common mode currents are a mathematical convenience which make certain analyses simpler. But I see that it also generates a huge amount of confusion.

The differential current is defined as:

1/2 * (I1 - I2)

and a common mode current as:

1/2 * (I1 + I2)

One of these is simply the average of the two currents. The other is half their difference. (For some uses, the factor of 1/2 is dropped, but this doesn't modify the conclusions.)

If I2 is exactly equal in magnitude to, and opposite in direction of, I1, (I2 = -I1) then the differential current is equal to I1 (or -I2), and the common mode current is zero. If I1 and I2 are equal in magnitude and flowing in the same direction (i.e., are in phase), then the common mode current is equal to I1 (or I2) and the differential current is zero. Any other ratio of I1 and I2 results in some differential and some common mode current.

Depending on the connection of the source, we can modify I1 and I2 together or independently by modifying the loads. For example, suppose that we have a transmission line which has one conductor driven by a voltage source connected between it and ground, and the other conductor driven by another source which is the negative of the first, and connected between the second conductor and ground. If we put a single resistor between the conductors at the load end, we'll have a purely differential current. Or if we put equal resistors from each conductor to ground, we'll have a purely differential current. But if we put unequal resistors from the conductors to ground, I2 won't equal either I1 or -I1, so we'll calculate non-zero differential and common mode currents. (To get a purely common mode current we can put the two sources in phase, then terminate the other end with equal resistors to ground or a resistor between the conductors.)

What's the big deal, and what's all this about one "causing" the other? We have two currents, I1 and I2, period. Their values depend on the nature of the load. And the differential and common mode currents are simply calculated from their values.

That's about as basic as it gets.

If you can get to the splitter you can replace it with a 2 way splitter and
pick up some signal. 8-way splitters have about 11 dB insertion loss,
because the "splitting". A 2-way splitter will have about 3.5 dB loss.
Unused ports should be terminated with a 75 Ohm termination for TV.
If you are allowed to put the antenna outside above the top of your roof you
will likely gain more signal.

You might have some luck with a longer run of coax. There may be some
resonance in the feedline.
You might also have some luck with adding to or changing the RF choke or
balun at the feed point. If you are using a coil of coax at the feedpoint
as your RF choke you might try a large number of ferrite donuts instead.
Try the easiest thing first, like adding a 10' jumper onto the coax to see
if feedline resonance has anything to do with it.

The difference being: On the old tests, you at least had to know which formulas to apply to a given question. You also had to know how to do the calculations. With the modern tests - all that is required is a bit of memorization. There is no need to know how the answer was obtained.

Yes, as you describe it.

> Just moved to a home that was wired for TV.
> There are a total of 7 outlets connected to a
> TV antenna in the attic.

Good grief. You can test the attic antenna by connecting it directly (no splitters) to one TV. If it has a weak signal, then you might need an in-line amplifier (or put the antenna outside higher, or both).

> Some channels come in strong and some are weaker.
> I want to avoid a signal amp because of the video noise
> they introduce.

Unless there is something wrong with a particular TV Distribution Amplifier, it will do more *good* than harm. Weak signal is certainly a cause of video noise.

> Two of the seven outlets have televisions hooked up
> via RG6 coax.

Hopefully the other five are connected with RG-59 (as opposed to speaker wire, for example).

Assuming that you don't have seven TVs connected, and assuming that the seven cables originate at a central location, why not disconnect the unused outlets and use a four way amplified TV distribution amplifier ? Terminate any of the four unused outlets. Ignore the three least likely to be used cable runs (at least until you need them).

Good luck.

David, K1TTT wrote:
This may be "basic but that does not mean it is simple or obeys a single law like ohm`s or kirchoff`s."

Instability, complexity, and diversity of coupling are not contested. Contested is Tom`s statement that the common-mode is unrelated to the differential-mode. That is wrong. There are exceptions. Perfect balance can eliminate coupling. Infinite distance between circuits decouples them. Both extreme balance and distance are rare.

R = E / I , Ohm`s law, is the mutual impedance formula. Another word for formula is: "relation". The word "relation" implies a relationship between the variables.

Mutual impedance is also called coupling. The word "coupling" implies related. Coupled circuits are related by Ohm`s law as defined by their mutual impedance, E2 / I1. We can measure E2 at great distance and observe its fixed relationship (at least for a period of time) to I1. this proves coupling and that the variables are related.

Drive two metal stakes in the earth. Measure the resistance between them. Say it rains and the resistance between the stakes drops. The voltage to current ratio, measures less. This relation, the ohms resistance, has changed but not disappeared. A relationship does not have to be unchanging to exist and endure.

Best regards, Richard Harrison, KB5WZI

If you insist. The following equations were originally called the
Heaviside-Herz equations. They are an expression and distillation
of the work of several people, including Maxwell.

del cross E = dB/dt E is the electric field vector. The d's should be the
type used in partial differential equations
which my
computer can't reproduce. This is an
expression of
Faraday's law. B is also a vector.

del cross H = J + dD/dt This is a generalized expression of Ampere's circuital
law. H, J, and
D are vectors. The dD/dt part is Maxwell's
contribution.

del dot D = rho Gauss' law. D is a vector, rho isn't.

del dot B = 0 This isn't named after anyone, but just
expresses the belief that
there are no isolated magnetic charges.

Heaviside was able, after much work, to come up with these expressions because
of
the work of some nineteenth century mathematicians who invented his math for
him, and

who never get any credit at all. Perhaps you can name them, Reg.

Tom, W8JI wrote:
"---or many users, have learned about the non-fixed relationship between feedpoint voltage and voltage exciting the feedline in common mode."

Are you saying there is a non-linear relationship between applied voltage of a given frequency and the voltage appearing as common-mode voltage when the applied magnitude changes?

What would cause that?

In another field, cross-talk always sounded a lot like the signal which instigated the cross-talk regardless of the amount of coupling.

Best regards, Richard Harrison, KB5WZI

I agree but it's frustrating when I compare my loop to a dipole and the dipole whips it's tail in the broadside direction. Cebik describes a 44 ft dipole for 40-10m that has a nice broadside pattern on all bands. I've tried this little wire and it works great. He also describes an 88ft dipole for 80-20m with the same pattern. These will beat a loop in their favored direction and are much easier to erect.

I noted that Cebik never mentions the use of coax to feed a multiband loop while Dave Fischer was very adimate about using coax with no balun.

Question: How is the loop a "balanced antenna"? Looks to me like the concept of being balanced doesn't apply as it does a dipole.

I'm looking to make a portable antenna for 40-10 meters for one of the State QSO parties.

I would be driving to a remote site, setting up my rig and working away.

I have looked at a number of designs, and the Magnetic loop looks pretty interesting. I'd be able to plunk it in the back of my truck and set up on site, then tear down and move to the next county on my list as needed.

Most of the hams I know are using dipoles, inverted V's and some G5RV's.

Is the magloop just so much hokum? Or is it's major drawback the constant tuning, which is no problem AFAIAC?

I once did some comparisons when making some mobile coils and
antennas. As a criteria for "resonance" , I assumed maxismum field
strength. When adjusting for maximum F/S, and then comparing the
minimum SWR, I've noticed about a 10-20-30 kc spread.
That was with fairly primitive testing, but thats what I saw. The
difference was not enough to worry about. In fact, I use only a SWR
meter to tune my mobiles, and have never had any trouble. I can tell
where it's at fairly closely just by listening to the noise as I tune
the radio across the band. MK

> Compared with individual dipoles.

If they are at right angles, and little to no coupling, than the
bandwidth should be about the same. Only if you have some coupling
between elements are you likely to see a big change. And it would
almost always be to the higher band dipole or dipole's. Usually, you
will see reduction of bandwidth in that case, depending on the amount
of coupling. Even still , the bandwidth should be quite usable. MK

I have a substantial 2" ferrite toroid with ten turns of coax at the
feed point. Although the feed line is a little hot, it is not as hot
as the household AC wiring that runs near the antenna end of my house.

I have an extra toroid and could add it to my feed line, but the
closest I can now get to my feed point (not counting all the turns on
the first toroid) is around 8 ft. away. I can also put a second
toroid anywhere else along the feed line right up to the antenna
switch in my shack.

I will be putting similar toroids into the two AC lines that run the
closest to the legs of the dipole and are the hottest, and in all the
smoke detector lines.

RF chokes on the smoke detectors and other devices being affected will probably help. A few ferrite beads may be all that are needed.

There are texts written on rf interference suppression. It would not hurt for you to do some studying.

Without looking closely at the model, it appears from the impedances that you're near parallel resonance. At that point, the impedance can vary rather dramatically with very small changes in element length or loop circumference, and with small changes in source placement. This is often the reason for differences in results between programs -- MININEC based programs places sources at segment junctions, while NEC based programs distribute the source over a segment. Some programs do automatic segmentation, and differing segmentation can move sources and otherwise affect results in situations where small changes have a large effect. If a very small change in the model does cause a large change in results, expect to do some tweaking on a real antenna after designing it with the help of a model.

The point I was trying to make was that both cases can happen. Unless people understand that there's more than one possibility, they jump to totally false conclusions, like "The MFJ-259B doesn't work".

>That is why analyzers like the AEA that try to guess the sign of
>reactance by observing the increase or decrease in impedance with
>frequency make errors in guessing the sign about half the time.
>
The last AEA-CIA I saw couldn't make its mind up - the displayed sign dithered as you looked at it. For certain other impedances the displayed X value would suddenly jump from say +30 (correct) and stick at zero over a wide frequency range... which cannot ever be a true reading. I had wanted to review it for a magazine, but it was just too flakey.

In contrast the MFJ-269 sailed through the same tests, and worse ones. Accuracy was really quite good, especially for the moderate values of both R and X such as you often find for antennas. The accuracy is less good for very high or very low values of R and X, but these extreme impedances will make any bridge-based instrument sweat, and at least the accuracy falls off in an understandable way. I can live with that.

I get a lot of antenna questions from readers of my monthly magazine column. This isn't the first instance where there was doubt about the readings from an MFJ, but the readings proved to be quite correct. The real problem was about understanding antennas, or understanding what SWR is.

>I use a quarter to determine the sign of reactance, heads is inductive
>tails is capacitive. It works just as well once an antenna is
>involved.

Fortunately I know you don't really mean that 'flip' remark.

Antennas *are* understandable.

You will find that a simple dipole is adequate. In fact unless you need to/
want to operate in nets that are way out of the ham bands you will be able
to use a ham antenna just fine.

You will be required to put in 'X' amount of time on the assigned network.
AF needs 12 hours per quarter. I use my 75 meter dipole with a internal
tuner on the MP to operate way above 75 meters without any problem at all.

The only time a LP will/would be needed is if you get into phone patch or
long haul traffic nets. Assuming you can find any traffic that is.

One more example showing how people get in trouble by thinking the voltage across the feedpoint equals the voltage that drives the common mode impedance of the feedline.

Model an off-center fed dipole 1/2 wl long (in space) and hang a wire down it, and look at the voltage across a balun to force current to zero on the hanging wire.

A model of a 130 foot dipole offset fed with a 100 volt voltage source 50 feet from one end and a 1/4 wl feeder hanging perfectly vertical shows the voltage to null current to zero on that hanging wire, at the connection to the antenna, is about 255 volts.

Just by offsetting the feeder about 24% of antenna length, a balun on a 1/4 wl feeder hanging perfectly vertical from the dipole has to hold off about 255 volts of voltage when the voltage across the feedpoint of the antenna is only 100 volts!

This helps show how the simplistic view Harrison and others use is incorrect, and demonstrate why I say the voltage driving the common mode impedance of the feedline is not directly related to the across voltage of the feedpoint. The common mode impedance of the systems are also not related.

Cecil asked [rhetorically] -
> Is 50+j35 ohms resonant?

==========

No Cecil. But that's a characteristic of poor, ill-treated, abused, life-shortened, ALC-moderated transmitters and careless operators, not the antenna system.

In an attempt to dispel any confusion which may have been caused to other readers of these walls by your amusing response, I can only repeat that the input impedance of a tuned circuit (tuner+feedline+antenna) when at resonance, is purely resistive.

(To find the resonant frequency(ies) differentiate the impedance function with respect to frequency and equate to zero. Insert the resonant frequency(ies) back into the impedance function and it will be found, as near as dammit is to swearing, the series reactive component(s) of impedance is/are negligible.)

Regards, Reg, G4FGQ

870. Can twin feeder be put underground??

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-11 12:01:31 UTC
From: Chris Bartlett <Bartty@v21mail.co.uk>
Message-ID: <3d2d73a4$1_1@news.greennet.net>
Source record: 138824

I have just run a 2 " conduit down my garden, about 20 yards to a convenient tree. The feeder from my G5RV is near this tree, I have run the coax and there is an excess of twin feeder from the G5 that can touch the ground unless I support it back up in the tree a bit as I am doing now. I have tried pulling the coax back towards the house and allowing the start of the feeder to go inside the plastic pipe. I find that I can tune across the HF frequencies using my MFJ 941 E getting low SWR on each band.

I understand it is best to keep twin feeder away from metallic objects as I had great difficulty when the feeder ran near a scaffold pole, it seems to be fine in the conduit under ground though.

I would be pleased to see any comments anyone might have on this. Constructive or helpful ones preferably.

Thanks in advance,

Chris.

Spacing two chokes 1/4WL apart (~234/f) is often effective.

Tom, W8JI wrote:
"Just by ofsetting the feeder about 24% of antenna length, a balun on a 1/4 wl feeder hanging perfectly vertical from the dipole has to hold off about 255 volts of voltage when the voltage across the feedpoint is only 100 volts."

Tom now introduces a new topic to divert attention and behold, a balun has a voltage drop, antenna impedance is a function of position, and an off-center-fed antenna is unbalanced.

The argument is and has been:
Is the common-mode voltage on the feedline related to the differential-mode voltage between the feedline conductors?

In Tom`s new example, does reducing the transmitter output reduce the common-mode voltage?

Does increasing the transmitter output increase the common-mode voltage?

A yes answer to the two questions above indicates that, yes there is a relationship between differential and common modes.

Best regards, Richard Harrison, KB5WZI

> voltage of the feedpoint. The common mode impedance of the systems are
> also not related.

Tom, if you choose two resistor values at random and install them in
the same circuit, are those resistors related? Of course they are.
Their random relationship disappears when you install them in the
same circuit. You apparently continue to be ignorant of the definition
of "related" even though I have published it more than once in the past
few days.

Even though the common mode impedance may be unknown, it is in the same
circuit as the differential mode impedance and therefore, is related.
Again, from Webster's:

"related - connected by reason of an established or discoverable relation."

The established relation is a common power source and that they appear in
the same inter-related circuit. The discoverable relation is that common mode
conditions can be measured. You continue to choose to use an incorrect word
to say what you are trying to say. The result continues to be a false statement.
Repeating it 1000 times will not make it true.

Source record: 138915

CAM wrote:
>
> Time for a checkpoint. Normalize the following seven values of
> resistance and plot them on the horizontal line on a Smith Chart
> normalized to Z0=300.

20+j0 ohms, .066

50+j0 ohms, .166

100+j0 ohms, .333

300+j0 ohms, 1.0

600+j0 ohms, 2.0

1200+j0 ohms, 4.0

3000+j0 ohms 10.0

I'm beginning to see how this thing works. Without the "normalizing"
you can't get started. Normalizing makes the chart useful at any Zo,
makes it a universal tool. One must keep the frame of reference for each
solution (Zo=300 in this case) to know where you're at.

I didn't use an antenna tuner, Reg, so I had to settle for impedances like
50-j10 as the minimum SWR point. The SWR was 1.2:1 indicating non-resonance.
Is an SWR of 1.2:1 enough of a mismatch to worry about?

> In an attempt to dispel any confusion which may have been caused to other

Yep. Move your antenna away from the house at least 30-40 feet. Works wonders.

I always had RFI problems when I had antennas close to the house. They induce RF into the house wiring and it goes all over the house working its magic in the many susceptible houshold devices. My solution was to move the antennas. Haven't had RFI since.

mag loops work well. but they have to be constantly retuned, there are lethal
voltages present
on them when running them with very much power, so physical contact is a big no no.
because of the high voltages that are present, the tuning capacitors can be very
expensive
if you purchase them. do a google search on loop antennas, there is a ton of infor
available.

> solution (Zo=300 in this case) to know where you're at.

Exactly, we are dealing with a characteristic impedance of 300 ohms so the 1.0+j0 in the center of the Smith Chart equals 300 ohms. As you calculated above, 50 ohms appears at 0.166(7) on the horizontal line. If we were dealing with a characteristic impedance of 50 ohms, 1.0+j0 would represent 50 ohms and 300+j0 would appear at the 6.0+j0 point on the horizontal line.

Did you plot the above points on the Smith Chart? Except for the uneven spacing, it is just like plotting points on the 'X' axis of a normal X/Y graph. The Smith Chart has gone through a transformation that causes the 'X' axis and 'Y' axis to be curved. The first installment showed how to locate a resistance point. Tonight I will post an installment that shows how to locate the reactance point along with the resistance point on the two-dimensional Smith Chart graph. Knowing how to normalize and locate points on the Smith Chart is the first step toward turning a Smith Chart into a very useful tool. The thing I find most useful about it is that it is a math model of transmission lines that I can carry around in my head and use in my thought processes. later ...

Cecil I noticed something odd while plotting the normalized impedances on the resistance line. Those to the left of 1.0 don't correspond exactly to the SWR results before normalization, that is in the case of 20+j normalized to 1/.06 yields SWR of 16.666 instead of the result of dividing 300/20 = 15. Is that significant?

Those to the right of the 1.0 point seem to almost all correspond with the exact SWR before normalization. Maybe that's all a mathematical anomoly, of no significance?

Oops, I see the problem. It's the result of rounding off the decimal, ie originally was .06666666666 instead of .06. It's not significant, that's as close as one can chart it.

> Sounds like hyperbole to me, Reg. :-)
==========
But Cecil, if you think it is not intended to be taken literally, why disagree with it.

As you (in the plural) are fully aware, the condition associated with "Must, must must" is that the input impedance must be purely resistive.

It is NOT associated with the condition that an untrained operator must have changed bands and omitted to readjust the tuner.

Just for once Cecil would you do me a favour by allowing me to win this argument.

Yours Reg. G4FGQ

That's not "rounding off", that's truncating. If you wish
to round off to 2 decimal places, it's .07, and the error - tho'
still there -- will be less (and to "the other side".)

Hi Chris,

The simple way would be to measure the range of SWR's offered and
compare them to the published values of others. If yours show a close
correlation - keep on truckin'. If yours don't and you've got
excellent matches where others fail - something is spooky. If yours
don't and nothing improves after you cinch up the antenna into the
tree - take your choice and keep on truckin'.

That was going to be posting #3 but you have discovered one of the
handiest things about using a Smith Chart for ham antenna systems.
It is a mathematical function of great significance.

Source record: 138831

While I can't provide an answer as to whether or not it is acceptable to operate with twin feeder that close to ground, I do have a comment on "antenna tuners". The only thing a "tuner" that is located at the transciever does is provide an impedance match to the end of the feeder and tune out any reactance there. It does nothing to change the swr between the antenna and the "tuner". If you have 10:1 swr at the antenna and then place a "tuner" in the line and tune for 1:1 swr as indicated on the "tuner's" swr meter, you will still have 10:1 at the antenna. I prefer to call them a transmatch as that is there function and they work well to optimize your transciever output by tricking it into "seeing" a well matched load. In this situation, high swr (up to a point) is not a problem if your feeder losses are low, as the reflected power will make it's way back to the antenna.

Dick Carroll wrote:
> I'm beginning to see how this thing works.

It's not all that difficult to understand. It's sorta like Morse code. Once you use it you might like it. :-)

We have learned how to plot a pure resistance on a zero reactance line, i.e. the purely resistive horizontal line across the middle of the Smith Chart. The Smith Chart is a two-dimensional graph, similar to the standard X/Y graph that you did in high school. The difference is that the 'X' axies are bent into arcs of circles and the 'Y' axies are bent into circles. When we locate an impedance point, we will normally find the resistance value on the horizontal straight line and go up and to the right to locate an inductive reactance (sign is positive) and go down and to the right to locate a capacitive reactance (sign is negative). So this exercise is to locate the following impedance points on the Smith Chart. Remember we are dealing with a 300 ohm characteristic impedance so we normalize all our impedances to 300 ohms.

Normalize and locate the following impedance points on a Z0=300 ohm Smith Chart.

300+j0 (You've already done that one), 300+j50, 300+j150, 300+j300,

300+j600, 300+j1500, 300-j50, 300-j150, 300-j300, 300-j600, 300-j1500

where +j indicates inductive reactance and -j indicates capacitive reactance.

Hint: All of these points will lie on the R=1.0 circle. Each circle is an equi-resistance circle and each arc is an equi-reactance arc.

I can vouch for this. I use 5 parallel dipoles for 20mtrs through to 10mtrs.
Whilst the bandwidth is completely acceptable for the 20 to 12 mtr dipoles,
the 10mtr dipole only covers about 200Khz for an SWR < 2:1. I am sure its
something to do with coupling.

There is actually a fairly simple reason why there is a narrower bandwidth with parallel conductor, common feed multiband dipoles. It took only a few minutes playing with EXNEC to see why. Let's take the case of a parallel 80 and 40 meter dipole set. The 40 meter dipole consists of two (approximately) quarter wave long wires paralleling the 80 meter dipole wires. The 40 meter wire will typically resonate as an open quarter wave transmission line a little below the transmitting resonant frequency. The antenna feed point impedance at the quarter wave transmission line mode resonance is way different than what you would see with a 40 meter dipole by itself. This is the reason for the rapid rise in SWR at the low end of bands with paralleled dipoles.

I didn't see a mention whether the conduit is metal or plastic. I
assume it's plastic.

The fields around two-wire line fall off pretty quickly. I'd say if
you can keep it spaced at least as far from external conductors as the
line's wire spacing, you'll be OK if not optimum. Perhaps, of you're
not running other things in this conduit, you can find some of the
resiliant foam packing material and make some "donuts" from it to
more-or-less center the parallel wire line in the conduit. You can
probably even just cut discs of the material and make a slit in them
to just past the center, and slip them over the line at intervals.

Cheers,
Tom

There's Smith chart software that will do the normalization for you,
and in fact read impedances directly off the chart. I use WinSmith
which goes for a price, but there's also a freeware one that
originated with Motorola, and some other freeware and demo versions as
well. Have a look at http://www.sss-mag.com/smith.html and subpages
(a tutorial there as well!), or pick the Moto one up via
http://rf.rfglobalnet.com/software_modeling/software/25/452.htm (and
lots of other software there if you go back up the tree a ways...)

With the software, I get the nice visualization of the chart along
with the accuracy of compter calculations. (The WinSmith one, for
example, allows you to specify the attenuation of sections of
transmission line used in a feed system, and properly accounts for the
loss.) I haven't looked at all the others available...you may find a
free one that has pretty much all the capabilities of WinSmith.

Cheers,
Tom

899. Multi-band roof-mounted vertical fed with 450 ohm ladderline

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-11 21:33:02 UTC
From: Nico Vertriest <Nico.Vertriest@pandora.be>
Message-ID: <iQmX8.744$8o4.222@afrodite.telenet-ops.be>
Source record: 138841

Hello,

I would like to put a 5m vertical on my roof (10m high) and to feed it with 450 ohm ladderline. I would like to use it as a multiband antenna with a balanced line tuner. As radials I would put several lines of rotor cable having a length of 5 meters (6 lines, each having 8 conductors). I wondered what is the most efficient situation for the radials. Is it best to cut separate radials to resonance for the 20,17,15 and 10 m bands ? Or can I just use several radials 5 meter long, and count on the tuner for resonance ?

Thanks in advance.
73,
Nico

Well, Reg, I disagree with what seems to be your definition of
"resonant." Even though a (theoretical) 50 ohm resistor presents no
reactance, I do not consider it to be "resonant." In addition, a
system of a number of coupled resonators driving a load likely will
present a pure-resistive load at its input terminals at a number of
frequencies, but again I don't consider the system to necessarily be
"resonant" at those particular frequencies.

Cheers,
Tom

Doc:
Dave, W0MHS (he has a new call) is the guy who wrote the original Loop
Skywire article in Nov. 1985 QST. He insisted that nothing but coax was to
be used for the loop and allowed for RG-62, RG-59 and RG-58. He warned about
using baluns because they were "unnecessary". I've seen more recent post
from him and he still insist on using coax. We would all like for him to
explain his theory. I think he was some kind of RF engineer. I believe this
antenna is also described in the ARRL Handbook and uses coax feed.
A recent article in QST describing a sloping loop followed Dave's advise,
specifying coax use. This loop is cut for 40 meters.

Hi Cecil,

Well, gosh, I'm not sure here what's conventional wisdom and what's not. I have seen over the years a strong tendency of hams to want to cut their dipole (or whatever) so it's resonant all by itself. I'm just saying that radiation does not depend on resonance. If a .386 wavelength doublet gives you the radiation pattern you want and you can arrange to feed power to it efficiently, don't worry about "resonance". I guess Reg would define "feeding power to it efficiently" (matching it to your transmitter) to be "resonance" (of the overall system absorbing power from your transmitter). I don't happen to agree with that language, but I think the result is just the same.

I'd just like people to not get hung up on trimming antenna lengths, when they can accomplish the desired goals in simpler ways. In fact, I've seen you post some things in the past that address just the same thing: your ideas about putting capacitors across balanced lines at the right places to get a good match.

In summary, I _hope_ the conventional wisdom is swinging toward the understanding that the antenna structure's feedpoint impedance doesn't necessarily have to provide a good match to the feedline you're using to get an efficient antenna system with the radiation pattern you want. You can divide the problem into separate pieces that may interact some but can be addressed in a logical manner. That doesn't mean it's a piece of cake...getting acceptable broadband performance can be quite a challenge for instance. But I think there has been a tendence to over-constrain the problem by asking the antenna structure to do not only the radiating but the matching as well, or worse, to be "resonant" when that really doesn't matter directly. I _KNOW_ YOU know that from many of the things I've seen you post, but suspect many still don't.

Certainly your 40m antenna example isn't surprising to me...dunno if it goes against "conventional wisdom" or not. :-) (It's fun to look at all the off-center loops you get from a moderately complex antenna/matching system if you plot input impedance versus frequency on a Smith chart...)

Cheers,
Tom

Message-ID: <3D2E04AE.3060102@eznec.com>
Source record: 138846

I'd really worry about loss if I ran an open wire line for some distance when spaced that close to ground. This isn't the same situation at all as having the open wire line get close to, say, a rain gutter or other good conductor. And people generally use an open wire line only when very low loss is important. I suggest making some good loss measurements of your transmission line. What I'd do is to make a couple of 9:1 transformers on ferrite cores, and first measuring the loss of just the transformers back-to-back. You could use a wattmeter (like the Bird, or the QRP directional wattmeter that was in QST and the ARRL Handbook some years ago and appears from time to time in compendia) or the MFJ antenna analyzer. Then insert your feedline between the transformers and remeasure the loss.

Without the loss measurement, you might think the transmission line is working just fine -- your antennas will be nice and broadbanded, and quiet. And you might be discovering, without realizing it, how many stations you can work with QRP.

> Why would the maximum field strength occur at resonance?

There is no guarantee that it will. That is why an SWR meter should not
be relied upon to determine the best tuning for the antenna.

> Why would the maximum field strength occur at resonance?

In my case it's kind of hard to tell being all I used was a F/S meter and the SWR meter in the rig. Resonance of the antenna would be when the input impedance is purely resistive. At that time, I assumed max F/S from the mast/coil/whip would occur at the same point of tuning. But in comparing F/S to minimum SWR "including the matching device", I usually noticed a slight spread of a few kc's. Not enough to worry about, but not exactly the same freq though. But, like I said I used just garden variety tools, so it may have been a fluke in measuring. I think I also tried it without a matching device with low power and got the same slight difference. That was quite a few years ago, so my memory fades on it..I haven't tried it recently. The thing is, it's hard for me to tell which point of the two tuning methods was the point of pure resistance. I don't have an antenna testing gizmo.. MK

It can work, but a dipole strung between a couple of trees, or hung
off a short mast would be a good bit better. Use a tuner and ladder
line for 40-10 use. I've been building some loops, but all for
receiving purposes on the low bands. I built a indoor rotatable
circular 16 inch MW loop for my 706mk2g. Works like a champ and makes
my 706 act like a transoceanic. I'm getting 30-40 db nulls. Some
stations, usually groundwave, I can totally null out. Works from 500
to 2000 kc with the variable cap I have. My next plan is for a big 4
ft or so loop for mainly LF and low MW. I used Reg's rjeloop3, and it
came out fairly close as far as comparisons to the real thing. I had
to guestimate being I used a circle. His program uses straight
sides... MK

If you apply a fixed amount of power to an antenna, there's no reason that the field strength should be greater at resonance than at any other fairly nearby frequency. (The pattern, therefore the field strength, will change with frequency. But there's no peak or other anomaly at resonance.) Modern rigs, however, deliver their maximum power into a 50 ohm resistive load, and the delivered power drops off if the impedance is any different from that, even for SWRs that are too low to cause the normal dramatic decrease. So that would be the likely explanation of field strength that apparently peaks at resonance, although the peak would really be at the point of minimum SWR as seen by the rig, not necessarily at resonance (although the two are usually too close together to distinguish). I just want to make sure that people understand that there's nothing about an antenna itself that makes its radiation characteristics different at resonance.

Track down Rick WB6LNH. He ran a giant rhombic cut for 20 meters for the Marine Corp from a base in W6 land. It was pointed at Vietnam. It always gave a good signal. I understand even VOA came and took measurements. Everyone talks about giant rhombics, but as far as I know, Rick was the only to actually build one: 1000 ft on each leg.

I think he is active MM. Try wb6lnh@winlink.org.

Cheers Greg, ve0acr.

Hi OM,

US National Security Agency (remember the adventures of Ollie and Fawn?). This is an intelligence office for the White House reporting to the president. They don't give a damn about copyright, the copyright law has no enforcement law in it, simply compensation law (means you have to chase down the miscreants yourself).

The e-mail reading program is called Condor. E-mail is no security at all - more akin to a message floating in a bottle. Would we all be blessed as to have such a system you describe in a world where spam had to be copyrighted? ;-)

Building a variable capacitor for your loop antenna is easier than most may think.

See Pic: http://valveman.tripod.ca/Simplecap.jpg

First off go to your local dollar stor and buy a picture frame about 5X7 or there abouts.

Take out the glass since you will use it as your dielectric for your capacitor.

Next get two pieces of sheet aluminium 4X4. You can either have your local sheet metal shop cut them for you or get a pair of snips and do it yourself.

Adhere one piece of aluminium to the glass so it covers from an edge of the glass outwards. Use goop or similar glue. The tabs in the aluminium are for electrical connection and drive for the upper plate.

Find some wooden stir sticks and lay a row as shown in the pic. The top row will be placed so it creates a channel for the upper aluminium sheet to track. Again use goop or similar glue to make them pernament. Ensure you round the corners of the sliding aluminium sheet so it does not catch when moving in the track.

The top sheet will have a two holes in it. One for electrical connection of a wire and the other to tap in a brass threaded rod for the drive.

Although not shown, the drive is a brass rod connected to an old electric screwdriver. Limit switches can be put in but you can also make a mechanical stop by adding a spring to each end of the rod and taking down the threads on each end. When the cap reaches max or min the motor will still turn but the cap will not. The springs are used to push the plate into the threads to recatch when direction is reversed.

The capacitance has a great range as measured on my very accurate cap meter. Measured approx 10-200pF

You can of course make the capacitor as large as you like to give more capacitance if desired.

Since glass is the dielectric, the capacitor is very similar to a vacuum variable in voltage rating. And can easily handle 100W.

If you have further questions send me an e-mail.

robert931@sympatico.ca

I hope you found this helpful

From: "Peter O. Brackett" <ab4bc@ix.netcom.com>
Message-ID: <aglc94ift1@slb6.atl.mindspring.net>
Source record: 138859

Reg et al:

Oliver Heaviside is also one of my heros. An engineer's engineer no doubt about it!

Heaviside *invented* what is now known as the LaPlace Transform method of solving systems of ordinary differential equations.

After he first introduced his technique, it came to be known as Heaviside's p-transform. [p = d(.)/dt]

Apparently all of the *mathematicians* of the day, *poo pooed* Heaviside's technique saying it was without merit, incorrect, etc...

Apparently Heaviside's answer to the critiques of the mainstream *mathematicians* of the day was that he knew his p-transform was correct since it always gave the *right* answers. Oliver was never impressed by the self-important high priests of mathematics who themselves couldn't solve real world problems.

And indeed as anyone familiar with LaPlace Transform techniques can readily appreciate, his p-transform method not only gave the correct answers, but it did so with a whole lot less effort than the methods promoted by the mathematicians of the day.

Heaviside, either just couldn't *prove* that his technique was correct with a classical mathematical proof, or more likely... he just didn't care to do so.

The difference was that Heaviside was a *user* of mathematics, and not a mathematician. Sort of like today's scientists and engineers who are users of computers not computer scientists. Just as an earlier generation of engineers and scientists were users of slide rules. And come to think of it... back then we didn't need *slide rule scientists*. Why do we need computer scientists today?

IMHO... one of the biggest problems facing engineers and applied scientists today is the bullsxxxx being promulgated by *some* modern computer scientists who have presented the world with the *gift* of object oriented programming and all the bloatware, arcane terminology, and obfuscation, associated with that particular cult and its' high priests. What ever happened to *plain programming* like Fortran, etc...? Now we have folks who want to re-write perfectly good scientific/engineering software in object oriented languages, because it is the *correct* way to do it. Often when this is done, the software no longer gives the correct answers! Heh, heh... Most engineers and designers just want to use computers, they do not become blackmailed by the high priests who worship at the shrine of the digital

computer! Heh, heh...

If Heaviside were alive today, I'll bet he would not be using object oriented techniques!

Though my admiration for Heaviside extends beyond the p-transform it is one of the reasons that I choose to use the symbol "p" for the LaPlace Transform variable in any of my own design work, etc... rather than the *modern* symbol "s" introduced by the *mathematicians* once they had finally *legitimized* Heaviside's techniques. To be fair, LaPlace, certainly a theoretical physicist and mathematician to be respected, had foreseen Heaviside, but at the time I believe that LaPlace's technique was considered to be a curiosity by most "mainstream" mathematicians of the day and hence had remained inaccessible to most of the world of engineering.

Hail Oliver Heaviside, an engineer extraordinaire!

When "some channels come in strong" and "other channels are weak", the
amplifier is prone to cause problems related to front-end overload in
the receivers. The amplifiers often have too much gain, overdriving
the receiver mixer while making only 9-12dB improvement in the noise
floor (by overcoming losses in the 8-way splitter and distribution
cables). With modern sets the noise figure of the TV is likely to be
just as good as the pre-amp, so compensating for the splitter and coax
losses is all the improvement you can expect from a quality pre-amp.

This is the best case scenario, which assumes the pre-amp has a low
noise figure, adequate dynamic range, and no parasitic oscillations.
If you buy a cheap preamp, the odds are against it on all counts.

Use only as many splitter ports as you have TV sets. Next install a
good antenna outside, up high and in the clear. If the stations are
not all in the same compass direction, add an antenna rotator to your
shopping list. Use the pre-amp only as the last resort, not the first
line of attack.

I'd be more concerned about the safety aspects of twin line feeders at ground level. They should be out of reach, just like the power line running to your house. Convert to coax (or two coax cables in "push-pull") before coming to ground level. Or keep the entire feedline safely out of reach.

The TV Distribution Amplifiers available at your local Radio Shack typically have 10 to 20 dB gain and four outputs. In other words, not too far from 'gain neutral'. Their slightly more expensive model (around Cdn$40, or US$25) even has adjustable gain. It is hardly as doom and gloom as your posting indicates.

I see your confusion. I didn't recommend a "pre-amp". I recommended a "TV Distribution Amplifier". Your concerns towards a 30dB gain pre-amplifier (Radio Shack sells those too...) are certainly justified, but that isn't what I recommended.

Hi Ralf,

Very interesting. Could you further describe the OCF antenna, the FD4?
I'm curious about how many elements it uses and their approximate length
in terms of wavelength. Does it use elements cut a percentage of a
wavelength off that which would be the center of the band, or what
scheme is used? Do some elements work on multiple bands?
That antenna might be useful for lots of hams who have to use
unobtrusive or hidden antennas but who want to work multiple bands.

My reference to "insignificant" was to the decimal impedances plotted
to the left of 1 on the resistance line which I referred to as "rounded"
and Jonesy correctly noted were, instead, truncated.

One of the great urban legends:

Gresham, OR, Aug 1996 -- The Portland Oregonian states a man wound up in the hospital, but didn't know exactly what happened to him -- He was talking with friend, then turned to leave, and "the next thing he knew the antenna on his 1984 Pontiac Fiero was up his nose." The article states that the antenna "pierced his nasal membrane, his sinus membrane and entered his brain cavity, where it destroyed his pituitary gland."

References:
www.google.com/search?q=1984+fiero+pituitary

My car has no external antennas. They're all embedded. I feel much safer that way.

931. lightningbolt 2 element quad

Hi,

Have a question about the Lightning Bolt 2 Element 5 Band Quad. For those of you who own this antenna, does it have 5 feedpoints (i.e one for each band) or does it have one feedpoint for all 5 bands. I have a friend who has one of these quads and his has seperate feedpoints for each band but his was destroyed in a ice storm and had to rebuild it and I think when he rebuilt it he made some modifiactions to it. Lightningbolts website doesn't give that much info on it. I suppose I could call them tomorrow and ask. But I thought I'd ask here first.

Thanks,

Matt

Yes, try it without the balun and see if it improves. When I got on 6
I put up a dipole with a commerical balun (can't remember which one)
and just could not get it to play well, likewise with a direct feed
from the coax. Just could not get a respectable VSWR on either one
and my signal was just not getting out well. Ended up using a 1/4 wave
matching stub as shown in the ARRL Antenna Book, 17th edition, chapter
26 figure 11A. This ended up working best for me, yes - there most
definitely are factors beyond the balun that can affect what happened,
this was not a laboratory environment. I guess that my point is for
you to pull the balun and experiment: you probably have enough coax
laying around to make a stub so check out the referenced book and give
it a try. Worst case is you are no further ahead - best case is that
your issue is resolved and you spent no more $$$.

Good luck & 73,
Howard KE6MAK

No, never had a day of law school or even a single law class, but it occurred to me that when even some of the old and famous hood ornaments have either been discontinued or modified to make them less hazardous in the event of an accident (e.g., by making them spring-loaded so they move out of the way instead of penetrating someone's body), these long, rigid, somewhat pointy things that many of us atttach to our cars could prove very attractive to ambulance-chasing lawyers.

If a car came from the factory with a Hustler or some kind of bug-catcher, would it comply with the safety regulations? I don't know; I am asking.

>of power as the dipole, since it has twice the effective aperture. But a
>ground plane (monopole) in free space will deliver very nearly the same
>amount of power as a dipole in free space.

Imagine you have two dipoles parallel to each other in free space, with
a transmitter connected to one and a receiver connected to the other. The
transmitter applies some amount of power to the terminals of the dipole it
is connected to. An EM field forms around the dipole. The other dipole
takes some amount of power from the field and delivers it to the receiver
attached to its terminals. Since the second antenna is receiving power
from the EM field, the field is changed by its presence.

Now suppose you remove the bottom half of the dipoles and instead
replace them with a perfect ground plane. We know about this analogy,
in particular we know we should be able to reproduce the same fields
in the upper hemisphere which existed when the free-space dipoles
were present, by imagining that the monopoles and everything we do
to them in the upper hemisphere is reflected 180 degrees out of phase
in the lower hemisphere. What transmitter and receiver powers are required
to reproduce that field?

To reproduce the field due to the transmitting antenna which existed
in the hemisphere the transmitter needs to apply only half the power
to the monopole, now worked against ground, that the dipole's transmitter
supplied. The analogy to free space dipoles says the monopole only
requires half the power to produce the field as there is a virtual
reflection of the transmitter supplying the other half of the power
to the other (virtual) reflected half of the free space dipole. In
any case, as it takes half the power to produce the same field in the
hemisphere, the gain of the transmitting monopole is 3 db higher than
the free space dipole. Everyone seems in agreement about this.

As for the receiver, the analogy to the free space dipoles says that
whatever happens between this monopole's terminal and ground is also
happening to the virtual reflected half of the dipole. This means
that whatever power the dipole's receiver was receiving from the field,
the monopole's receiver will be receiving half of that. That is, to
reproduce the field above the monopole's ground plane which existed in

that hemisphere between the free-space dipoles, both the transmitted
and received powers for the monopoles will be half that of the analogous
free-space dipoles, and the ratio of received to transmitted power
for the monopoles will be the same as that of the analogous free space
dipoles as is necessary for energy conservation if the field is
to be identical. And if I'm understanding how they define transmission
gain in the paper, I think the paper says that Mininec agrees with this
result (as do actual measurements?).

If we used the formula for effective area you are applying above, however,
we get a different result. We still can reproduce the transmitted field
over the ground with half the power applied to the transmitting monopole,
compared to the dipole, but the formula you are using says that since the
monopole has twice the gain and is in the same field as the free-space
dipole, the monopole's receiver will receive twice the power from the
field as the free-space dipole and the ratio of received to transmitted
power will be 4 times higher for the monopoles than for the analogous
free-space dipoles. This is 6 dB more then is predicted by NEC, according
to the paper, and would be expected by applying the reflected free-space
dipole analogy to the monopoles over ground. I believe this is the 6 dB
problem the paper is worried about.

The implication is not only that the conventional formula for effective
area when applied to monopoles over ground disagrees with Mininec, but
also that monopoles over perfect ground *do* *not* reproduce the fields
in the hemisphere that would be generated by the analogous reflected
free-space dipoles. Since I don't believe NEC and the reflection
analogy for perfect ground could both be wrong (the latter is in all the
books which reproduce the effective aperture formula), I think the
paper's assertion that the standard formula for effective aperture
does not work for monopoles over ground is probably correct.

After looking at the derivation of this formula, I think I too
believe it doesn't work for monopoles over ground. The formula
implies that the effective aperture of an antenna depends solely
on the antenna's gain and the wavelength being received, and
hence has no dependence on antenna's geometry or surroundings, but the
derivations of the formula in the books I have are all based on
considerations of free-space dipoles and just seem to assume it
works that way for all antennas. I don't think that assumption
is justified, and I think the paper's addition of a fudge factor of
4 to make the results match the values for monopoles over perfect
grounds is probably correct, if not all that useful since it leaves
one to wonder what the effective aperture of other antennas in other
environments might be.

>> Number 2) above was presented in the report as being "news".
>
>Number 2 would indeed be news, if it were correct. But it's not.
>
>It would appear that the purpose of the paper is to promote MININEC

>Professional rather than to present new information.

I don't think this is a wonderful paper, given the amount of work it took to guess what they where talking about, and I think there were better ways to prove their point than by comparing theory to Mininec. I do, however, think the paper is correct that the conventional formula for effective aperture does not apply to monopoles over perfect ground (it overestimates their effective area by a factor of 4), and I suspect it may not be correct for anything but dipoles. If you disagree with this I'd be very curious how you get the analogy between monopoles over perfect ground and equivalent dipoles in free space to work out, since it seems to me that either that formula or this analogy is broken.

I was reading on eham.net that someone used 72 ohm coax for a proper match when he made his seperate feedlines for the quad. Here is the quote.

"Lightning Bolt provides a balun for matching; all driven element wires are tied together then attached to the balun, which has a coax fitting. This is nice because there is no antenna switching necessary and it works fairly well except SWR is a little high and I am from the old school so I feed each element separately via an Ameritron antenna switch using 72 ohm matching coax quarter wave stubs."

Is this necessary?

Thanks,

Matt

Me too, Dick...I was there from '67-68 at the signal school and operated the ham station, k2usa, most evenings. Nice layout! Then I was fortunate enought to get sent to Korea, right outside of downtown Seoul on the Yeungson compound. The ham shack for HL9US was about 100 yds from my hooch and I got to use it every evening as well.

I got very used to the approximate 12 hour time difference between Seoul and the mid-USA. 20m was lotsa fun. No Rhombics there, of course, but they had a TA-36 up about 70' that did a fine job for us. About two miles away on the hill, the local "sniffer" people had a monster LP up that I always wanted to get my pinkies on....but we couldn't even get through the gate <g>

Rhombics sure are pretty, the physical area they cover makes them look awesome. They have the advantage of being simple to construct. They also have about the same input impedance over a wide range of frequencies, and the main lobe is in the same general direction.

On the other hand Rhombics have lower gain than we would expect for a certain beamwidth. They are somewhat inefficient antennas (often less than 50%), have low gain per acre of space compared to other antenna designs (like curtains or multiple yagis or logs), and have multiple strong spurious lobes that waste power compared to cleaner pattern antennas. They also gain-limit at about 3.5 wl per leg when mounted a wavelength or two high over real earth because of the inability to force significant current out to the ends due to radiation losses and ground losses below the antenna.

Log periodics are the choice now for lower gain applications, and curtains are the choice for higher gain or narrow patterns, when bandwidth is a concern.

Alan,

My Aunt Tenna poked her husband in the eye for studying a copy of
Hustler, and they actually slapped a Ham Stick on it to help the
swelling and black and blue marks go down.

By the, you find "antennae" on bugs. You find "antennas" on cars.
While it looks fancy to say Hustler antennae, that would only be true
if it were mounted on a Bug. On a Caddilac or a Escort, they are
antennas.

Peter's descriptive use of the English language is better then mine but here are a few extra comments -

Under the general heading of "More Quotations" there's a short note about Heaviside in my website. http://www.g4fgq.com

Heaviside's 'calculus' was publicly ridiculed by the English university academics of the 1870's and 80's because, in their eyes, it lacked foundation. It was a new sort of mathematics. It introduced new symbols. It could not be traced back to Pythagorus so it lacked rigor. It was therefore not to be used.

Heaviside KNEW from a practical viewpoint that it gave the correct solutions to important engineering problems of the day. He had no great incentive to provide rigorous proofs of his work just to keep the academics happy and gain their recognition. He had better things to do.

His response to criticism was "Shall I refuse to eat my dinner because I do not fully understand the processes of digestion?".

And the academics of the period, secure in their comfortable ivory towers, had no ideas to offer on the subject or the capacity for original thought.

It was American engineers and practical mathematicians, early in the 20th century (there are several well-known names), who discovered the proof of Heaviside's correct reasoning. The proof was deeply embedded in the century-old work of Laplace, the Napoleonic theoretical mathematician who, of course, had never heard of the electric telegraph let alone radar, TV and RG-58.

Heaviside's calculus was first known as the "Symbolic Calculus" from his invention of the symbol p = di/dt which means the rate of change of electric current, or anything else, at any instant of time. The academics were baffle-gabbed when Heaviside began tossing p around just like any other ordinary algebraic number. It was a veritable revolution in mathematics.

Heaviside used his sound intuition to write down such mind-boggling equations as -

A*p^3 + B*p^2 + C*p + D = 0

the physical meaning of which defies the imagination but which nevertheless has easily calculable roots. But how can such a monstrocity possibly be justified except on the grounds that it provides the right answers every time?

With a lot of juggling this is where Laplace enters the scene.

The symbol p, for the want of a better word, became known as an "Operator". Heaviside's calculus then became known as "The Operational Calculus".

In more recent years, to satisfy the academics, it has become known as "The Laplace Transform Method" which of course is misleading. These days it is even used by investment bankers in the field of the worrying ups-and-downs versus time and sudden shocks of economics.

Nico,

I suggest you make the radials the same length as the monopole. At a minimum I would use two, but four even spaced radials will produce a better omni-directional pattern with the antenna system that close to ground.

Although you will be feeding an unbalanced antenna with balanced line maintaining the same lenght for all the elements (vertical and radial) should result in lower level of common mode current on the transmission line.

The antenna will work fine. Go for it!

Tom, W8JI again wrote:
"That`s probably why you can`t give correct technical responses using Ohm`s law."

Coupling between circuits can be measured.
Coupling between circuits is stated as an Ohm`s Law ratio.

All Ohm`s law relations can have any number of E & I values with the same ratio. The numerator and the denominator are just multiples of the same number. This value of the ratio remains constant.

Coupling between circuits is determinable and can be written. It is a fixed value for at least an instant in time.

Best regards, Richard Harrison, KB5WZI

I wasn't trying to be fancy. I grew up in England, where these signal-gethering and radiating conductors were called "aerials," so the only plural of "antenna" I ever encountered was "antennae." On checking, I find that my son's Webster's agrees with you that "antennas" is correct for the devices under discussion. I have learned something.

Why do you say that? According to the ARRL Handbook, "Common-mode
signals" are defined as "signals that are in phase on both (or
several) conductors in a system."

If my 3-wire A/C wiring is picking up the RF from the antenna, why
would one wire be doing something different than the others as regards
RF? The hot (black) and neutral (white), at least, are the same
length. The ground wire (green), if the electricians could be
bothered, might have a longer effective length.

In any event, it appears that the most cost effective means of dealing
with the problem is to wrap the electrical wiring bifilar-style
(trifilar?) around a ferrite toroid -- which ought to choke off RF in
all three wires.

Well,

One could assume that a ham/cb antenna, particularly an HF whip would be too long for such a thing to happen. Also, most communications antennas are more flexible than that of a broadcast antenna and, unless the static ball is missing, less
likely to do as much damage. In all my years of fooling with radio, I have never
heard of such a thing happening until now. Even short VHF antennas (5/8 wave,
etc) are too long for someone to get the thing up their nose, and, again, if the
static ball was in place, the guy that was injured must've made some helluva turn
to do all that damage. I am having difficulty visualizing someone penetrating the
nasal membranes with a static ball. One quarter wave VHF antennas are usually
somewhat flimsy and would be too SHORT for this to happen if mounted on the deck like the AM/FM antenna. I don't say it didn't happen, or couldn't, but I have
never run into such a thing. This does, however, point out the need for us to be very safety-conscious with our mounts, braces, and hardware to insure that none of
it has protruding parts or sharp edges. Top hats should be above head level. Braces should be rounded off so there are no edges for someone to get cut on in a tight parking lot. I dont know about you guys, but I make sure to round off and remove all burrs on my installations. I worry more about that than I do of some-one closely "sniffing" my whip!

Oh everybody trying to be a card and never really answering the question. Yes, there are two studies.

The first one of internest has more to do with the dangers of RF from cell phone, two-way radio, antennas, and of all things, GPS antennas. You can do a search of the EPA site for this one. If my memory serves me correctly, it was 1997.

The "OLD" commerce commission did a study in the mid 50s as two way radio and car phones were just getting popular with the business sector. The original white paper was published in the Congressinal Record, so someone out there should be able to pin it down. Whether or not it speaks of impalation I can't say.

Once upon a time early in my career, I was a cop for about 5 or so years. In those days, AM radio antennas were usually tubular, not stainless steel rods like they are today. I recall a pedestrian who got her arm severed by one, but the nucklehead that hit her was going over 80 at the time.

I've been mobile for over 30 years, and I don't know of any cases other than the one I cited.

I guess I'm different. Why not feed the thing with coax? The losses at any reasonable length are not that great, and you wouldn't have the balun to worry about, which if not designed specifically for 6 M could be a great source of loss.

Secondly, verticals are great "IF" you can get a good ground plane under them (and a dozen or so wires isn't a ground plane). If I needed a 6 M antenna, I'd put up a halo, or a stacked pair of halos. No ground plane needed, and they work well, even on an automobile. Cheap too.

Roy gave you the best solution to measure the loss, but Roy would agree, not all hams have the necessary "tools" to do this job correctly. One respondent also talked about the losses in the tuner/coax feeding the antenna, and he's correct as well.

However, the G5RV is usually close to resonance on most bands so the VSWR really isn't that high, and the additional losses in the coax not that great. But like Roy stated, you don't know what additional losses you have laying the ladder line on or near the ground, and it's what you don't know that gets you every time.

If for no other reason, you need to get the line away from surrounding objects, and where some one can't touch it.

Modeling a five-meter monopole using four five meter long evenly
spaced radials with base height of 10 above ground. The following are
VSWR values reported by NEC for 50-Ohm coax.

MHz. VSWR

14 2.4
18 4.7
21 8.3
25 11.3
28 11.2

It would appear that 21 MHz and above could have substantial losses if
coax was used - depending upon the length and loss specifications for
the line.

>
>Secondly, verticals are great "IF" you can get a good ground plane under them

That may be true for ground mounted momopoles, but for base heights of
ï¿½-wavelength or greater above ground four radials are enough.

Matt,
It can be fed either way, although a common
feed point for a 5 band antenna can cuase some
problems. For instance, the 20 and 10 meter
elements will interact, so will the 30 and 15
meter elements.
If I had to make a choice I would use a seperate
feed line for each driven element. Maybe use a
remote switch to keep the long runs to a minimum.
You would only need a short feed line from the
feed point to the switch.

Don`t bury your signal.

We needed a dummy load for 50KW and 100 KW transmitters. Did not have enough stainless steel for a traditional dissipation line. Instead, we built a knee-high copper open-wire line, width adjusted to maintain 600-ohms at such a low height. We didn`t have to run too many yards (metres) of that trip-wire to soak up most of the 100 KW at h-f. It was a real earth warmer and worm turner.

Building a capacitor that has very high Q, high voltage breakdown, and
a wide tuning range, necessary for high efficiency and wide frequency
coverage, is much more difficult than people might realize.

I tried sliding plates and flapper plates without sucess, as well as
coaxial capacitors. I'm sure a multi-layer coaxial capacitor would be
effective, but it is a bitch to build.

The capacitor is probably the most difficult part of the system,
because of the high voltages and high currents in an efficient loop. I
used butterfly plates and dual welded stators in a boxey shaped
capacitor.

Most of the articles on the Bobtail Curtain suggest a feed point at the bottom of the center vertical element. Since the bottom of this element is quite some distance above ground, and the shield of the coax is to be grounded, what is the best method for attaching a ground at the feed point of the antenna?

I have also found a corner feed method, but have the same question regarding the shielded part of the coax to ground.

Thanks for any help.

Why would equal length radials and vertical result in lowest common
mode excitation Dan?

The common mode excitation of a zepp antenna at resonance is not
extremely high when one terminal of the feedline is hanging open.

Think of his antenna as a J-pole, and it will help you find a
solution.

I would expect shorter radials and a longer element would be better in
most cases, because the most difficult goal is to have equal voltages
on each terminal of the antenna, with respect to the path the ladder
line takes, along with equal and opposite currents in each conductor.

The ladder line, in such a system, almost always radiates
significantly unless you pick a "sweet length" of ladder line.

> the free space dipole. Everyone seems in agreement about this.

Using a ray approach, rays can be visualized as emanating from each
point on the monopole. At any point in space, field contributions from
2 rays will add as long as their phases are about the same. From image
theory, the ray reflected from the ground plane can be visualized as
emanating from the virtual half of the dipole in the lower hemisphere.
For identical current, each segment of the transmitting
monopole radiates twice as much field as the dipole. Or to get the
same field,
half the power is needed. The result is that the transmitting monopole
gets to
take advantage of the ground plane reflections and gets a higher gain
value.
We're agreeing here - this is only a re-statement of your analogy.

> As for the receiver, the analogy to the free space dipoles says that
> whatever happens between this monopole's terminal and ground is also
> happening to the virtual reflected half of the dipole. This means
> that whatever power the dipole's receiver was receiving from the field,
> the monopole's receiver will be receiving half of that.

I was OK with the analogy up to this point. But why wouldn't the
receiving
monopole also get to take advantage of the ground plane reflections
and also
have a higher gain value? In effect, each point on the monopole can
receive
in-phase contributions emanating from one point but arriving from
different
directions, i.e., the direct ray and the reflected ray? Looking at it
this way,
the monopole with twice the gain would receive twice the power.

That is, to
> reproduce the field above the monopole's ground plane which existed in

> result (as do actual measurements?).

It's not clear from their paper how exactly they did their modeling to
get the transmission loss. Did they do the excitation in the
monopole-monopole case so that the incident field is identical to the
field in the dipole-dipole case? Or did they keep the excitations the
same and get higher incident field? They didn't say. They also didn't
compare the theory to measurements which apparently was what caused
the discrepancy in the first place.

> The implication is not only that the conventional formula for effective

> environments might be.

Apparently, what they're doing is trying to use the Friis free space equation to
compute the received power for various antenna combinations, and that's why
they're using MiniNec to verify theory (usually it's the other way around).
I've seen other studies with a similar goal, and good agreement between
measurements and predictions is found when a gain of 2.14 dBi for each
monopole is used. Maybe this is one case where the free space equation is not
applicable.

>can I just use several radials 5 meter long, and count on the tuner for
>resonance ?

Nico,

Even antenna systems that are not perfect can make us very happy, so
it might be worth a try.

Fiorst, if the radials are in a closed tight bundle like a cable they
will not behave like their individual lengths. You might or might not
get into trouble depending on the way the wires interact with each
other.

The fortunate thing is the feedline and antenna will both radiate, and
you may not need much of a radial system at all anyway. The
unfortunate thing is you might have RFI problems with the system.

Why not try it, and see how it works??

If it works, you are a winner.

If it does not work, then some question and suggestions might help
you.

Howdy,

I would like to obtain a telescoping or collapsing whipantenna that can be mounted on a travel trailer and has a minimum length of 30 feet.

Before you get all excited I don't intend to drive down the road with it extended.

Is there such an antenna available? Where?

Tnx es 73 de Jack, K9CUN

If common mode conditons are unrelated to anything else and are
completely random, how can there possibly be a "sweet length"
of ladder-line? :-)

I use the DK9SQ fibreglass telescoping mast. You could easily fasten a wire to it. Its 33ft long (ideal quarter wave on 40m) and telescopes down to about 4ft. I'm sure you can get it in the states (Kanga USA??), try a search on DK9SQ. Ideal for portable work - I've bought two.

From: lepton@sympatico.ca
Message-ID: <399debb7.0207121409.490576e4@posting.google.com>
Source record: 138727

Hi

At 13.5 Mhz, what can be the needed power to produce a magnetic field
of 42dBuA/m at a distance of 10 meter with a dipole.
I know this is far field and i have no software to help me on that.
At the same time, what can be use to compute the needed power for a
dipole, and a ground plane ?

Any help will be welcome.

Thanks a lot for your collaboration

Gilles

I already answered it. As a matter of fact, the reason you gave an incorrect conclusion is at the root of what I am saying.

Your calculations may be fine, but your results or conclusions are incorrect as a general answer. You (like many people) incorrectly assume differential voltage **across** the feedpoint, or the differential impedance of the system at that point, is directly related to the voltage driving the common mode impedance of the system.

I gave several examples showing where the common mode voltage can be several times the differential mode voltage of the system.

The fact Ohm's law works does not mean we can incorrectly apply it to a system and the answer is correct. The common mode impedance is NOT directly related to the differential mode impedance, and so the voltages are also unrelated based on the differential mode impedance alone.

Let me try one more example, in general terms.

I can have a feedpoint **differential mode** impedance of 100 ohms, and apply 100 watts. According to your (incorrect) application of Ohms law and the formula for power to the example I gave, you would conclude voltage driving the common mode impedance of the transmission line would be 100 volts or less. In a perfectly balanced case with a balanced line, you assumed each antenna terminal would have 50 volts, and common mode problems would be minimal.

In truth, the actual voltage from each respective antenna terminal to "ground", or more properly to the transmission line systems common mode impedance, can be anything from zero volts to any amount of voltage up to whatever impedance limits the system has.

A system could easily have 10,000 volts between each terminal and "ground" (or some other reference point for the feeder's common mode impedance) or a very low voltage, the voltage you gave is only correct in one set of very limited conditions..not as a general rule.

There are many antennas that have problems like this. These are the systems that trip people up, and make them think they don't need much of a balun when the system..in fact...has a huge problem.

If you want a more specific example, I can give one. But only if you are willing to listen and learn how these systens actually work, and not argue nonsense. I think it is important that people understand this, because it is thinking like yours that causes people to assume a low differential mode impedance always makes life for a choke or current balun "easy".

Since you have elected to follow me around from thread to thread and give incorrect responses, I have only two choices. I can show you how you are incorrect, or I can ignore you and hope you find something better to do than bother me.

So is Roy's article, "Baluns: What They Do And How They Do It",
wrong? Seems the differential current emerging from the inside
of the coax braid has two paths it can take, one toward the differential
load and one down the outside of the coax braid toward the common mode
load. One would think those two currents would be related to those
two impedances by something like Ohm's law or Kirchhoff's law.

I built a 40 meter version once and the feedpoint was about 8 feet above
ground. The feedpoint was 'suspended' in mid-air and I ran a ground
wire directly down to the ground. It wasn't a permanent installation
and it worked like gangbusters...in its favored direction.

> of the antenna?

Probably the most common feed method is to extend the center element down to the matching unit located at ground level. The matching unit is usually a parallel tuned LC tank with the 'cold' end grounded via a ground rod or small counterpoise system. This feed method is simple and works reasonably well as long as the bottom of the vertical elements is less than approx. 1/8 wavelength above ground level.

A better way is to elevate the matching unit to the bottom of the center element and provide a low impedance return for feed currents by using a balanced counterpoise. Two counterpoise elements are usually sufficient, and ideally should run perpendicular to the plane of the curtain in order to minimize the horizontally polarized far field radiation components. Various strategies are available for minimizing pattern disruption arising from feedline common mode currents. One good method is to have the counterpoise wires carefully balanced and approximately 3/8 wavelength in length. The feedline should be link coupled to the LC tank for maximum common mode impedance.

Choosing the length and number of counterpoise wires is a tradeoff between minimizing common mode excitation of the feedline, insuring minimal horizontally polarized radiation and cost/asthetics. Minimum common mode excitation of the feedline is achieved when the voltage difference between the counterpoise system (at the 'cold' end of the matching unit), and ground is minimized. For any number of counterpoise wires this situation occurs at quarter wave resonance. The problem is that the amplitude and phase angle of the counterpoise currents are most sensitive to small variations in length at resonance. Unless you are able to measure radial current amplitude and phase, it is usually better to shorten the radials a bit in the interest of maintaining balance, at the expense of higher common mode excitation.

Another variation is to replace the counterpoise wires with shorted quarter wave stubs of open wire transmission line. This is a symmetric version of the classic Zepp (Jpole) feed system. Coupling to the feedline is accomplished by an inductive link at the shorted end of a stub. Usually the link takes the form of a small loop taped to

the open wire line.

I'm a amateur, no sci, not legal, nothing to lose

If the EH antenna is a hoax, it's fun to work with !

I've seen a LOT of threats about the EH from people without testing
it.....
Tom and a other guy(I don't care), they do the testing of some strange
stuff on a computer, They don't do field stuff anymore, if they
already did that anyway !!!!
Testing a antenna on a computer ?????, they never work !, I know !
A antenna must be build and correct, otherwise they don't work
The 160Mb antenna was't correcly build, every body can see that !, a
sloppy job !
Of course it wouldn't work !

What computers say and the books is right ??????
2002 years ago a guy is nailt to a cross for his beliefs.......
So you know what is right??????

I've tested the EH antenna, I think is working great (I don't know
why, but it is !), not "sci".
Maybe it's a short dipole, I don't care, it works great !

Because I'm a pirate, I can't do anything wrong, and must have a
pretty good transmitter (No broadband amp.) (no EMI, LFI)
I allways testing my signal with a spec. amd osc. for harmonics and
modulation.
not 100% perfect it goes down !

The EH antenna works for me, the same as a dipole on 6.4Mhz, I don't
care why it does !

Everybody who says it a hoax hasn't build one to test it and aren't
amateur but "paper guys", only what the computer says is good ??????

For a couple of euro's you can buils it your self and test it !!!!

Or a you scared to do something (with your "ford perfect") to test
something new ??????

No :, computers are a fun thing, don't believe them

Please read the article again. It's the current on the inside of the outer conductor, not "the differential current" which has two paths it can take. One is to one side of the dipole (or other antenna), not "the differential load" and the other is down the outside of the coax braid. It is true that the current on the outside of the braid is a purely common mode current.

There are three currents on a coax feedline: one on the outside of the inner conductor, one on the inside of the outer conductor, and one on the outside of the outer conductor. The two inside currents are purely differential, i.e., equal and opposite. The outside current is purely common mode -- there is no other current which creates a field that can cancel the field it generates. The outside current can be modified without any appreciable effect on the inside currents.

A twinlead feedline has two currents: one on each conductor. Common mode and differential currents are mathematical combinations of these, as I detailed in an earlier posting.

Hi Tom,

Well, my thinking was along the lines of say using an example of "L"
antenna with both elements lengths the same and feeding at the 90ï¿½
junction. That seemed somewhat more balanced to me that having the
elements different lengths to me. (I know it won't be exact due to the
elements relationship to ground.) Next added an additional three
elements (the same length) at the base forming a radial system - still
seemed (current wise) to be somewhat more balanced than if the lengths
varied. I would think that say if 1 amp at the feed point at base of
the monopole and +/-0.25 amps in each of four radials again at the
feed point at the base current should be more balanced for feeding
with ladder line.

I was also assuming that the antenna system was raised where the base
of the monopole was 10 meters above ground.

So where did I go wrong?

BYW: I did say "should" <grin>

This method can be improved considerably by inserting a series
capacitor of approximately 750 - 900 ohms reactance in the center
element. This capacitor is positioned such that the impedance of the
center element looking 'upward' through the capacitance is
approximately 800 ohms resistive. The wire extending from the
capacitor down to the ground then acts as a single wire feedline
terminated in it's approximate characteristic impedance. The current
in the feedline still contributes to the vertically polarized field,
but careful selection of parameters can result in very nearly the same
total field generated by the center vertical element as in the ideal
binomial case. The impedance of the single wire feedline will be
around 800 ohms resistive and can be matched either with an LC circuit
or broadband transformer. This method works reasonable well with a
small buried counterpoise or ground rod and has the practical
advantage of greatly reduced voltage present at ground level.

Hi Willem,

Anything will work. The question is - how well does it work?

Please tell the world about your test results, the sort of site, the date
and other relevant info.

How were the tests made, instruments used etc. In the absence of expensive
commercial equipment, home-made gear will be quite acceptable.

Elementary methods will suffice. You don't need to be a rocket scientest to
be convincing.

Just provide some numbers and a page of text describing how they were
obtained.

I guess a week would be sufficient to produce a report.

Yours in anticipation.

Roy Lewallen wrote:
"The outside (of the coax shield) current can be modified without any appreciable effect on the inside current."

Energy to the outside of the shield comes from the same place that the energy to the so named antenna comes from.

Where is the return path of the current on the outside of the shield? Answer, there is none unless there is an unbalanced antenna connected to the coax even if the coax itself makes part of the antenna.

Since all power inside the coax is differential and this power includes that supplied to the common-mode, the total power taken from the coax can`t change and not change current inside the coax.

Another analogy: A river splits into two outlets flowing into the sea. One outlet can`t be blocked without affecting current in the mainstream and the remaining outlet.

Common-mode current isn`t blocked or altered without affecting differential-mode current in a given system.

Concocting a system to change the common-mode without changing the differential-mode would be an oddity.

I won`t say it`s impossible because with impedance transformations we can have various currents that represent the same power. But that is outside the connections in this thread.

Best regards, Richard Harrison, KB5WZI

Tom, W8JI wrote:
"I can have a "differential mode" impedance of 100 ohms and apply 100 watts.---you would conclude voltage driving the common mode impedance of the transmission line would be 100 volts or less."

I won`t speculate what the driving voltage might be. You may have a 100-ohm transmission line 100 miles long for all I know.

I will say that 100 watts into 100 ohms practically limits your voltage at the load to 100 volts maximum as you have no other power source. You may have a tuned circuit with a Q of 100, and it is just a high impedance at its resonant frequency shunted in some way across your parallel 100-ohm load. At resonance, at least a parallel resonant circuit of high Q, won`t sap the source much.

I suggest using the kw rated loading coil on Hustler antennas to reduce total impalement. However, the extra weight of this coil has been know to cause SUVs to flip over while parked.
As for eye poking HamSticks, car radio antennas appear to be a great threat, especially the retractable type of which some victims had been injured while setting over the hidden antenna while the driver turns on the radio.

The current on the inside of the coax braid is not the differential
current? One side of the dipole is not part of the differential load?

Maybe if it were struck by lightning.

So much mis-information, so little time!

My example calculated 1800 watts from 300 volts across 50 ohms. You have no voltage multiplier. High impedance only limits the current accepted. The only voltage source is your transmitter. There is no Tesla coil anywhere.

The most a transmission line can do is to double the voltage at the end of an open-circuited line. That`s because the only place for the H-field energy to go when the circuit is interrupted is into the E-field for a short distance.

2 x 300V = 600V. That could happen at the end of an open transmission line, using 300V as the incident voltage on a lossless line.

I did assume a typical in-line pre-amp. A good quality distribution
amplifier is much better suited for the job.

But it's essential to have adequate signal at the amplifier input. No
amplifier can do better than the S/N ratio at its input. That's why I
suggest upgrading the antenna before adding RF gain.

Why are you going back to current Cecil, when I am talking about
impedance and voltage and that is what Richard responded to??

I don't think currents have ever been in dispute, nor have I mentioned
them. Why dredge them up??

The balun must allow a certain terminal **voltage** to appear at each
load terminal, otherwise common mode current will appear in the
system. Even small amounts of common mode current can cause big
problems elsewhere in the system. For example, only a few hundred mA
of common mode current will cook a bead balun.

The voltage and impedances can have any relationship (which to me is
the same as saying they are "unrelated"). This is the fact people miss
when they assume (as Harrison did) a 100-volt (or whatever)
across-the-feedpoint voltage means only 100 volts are available
across the choke balun.

We see this problem time after time. People only worry about
differential mode impedance or voltages, and it fools them into
thinking a balun has an easy job when the common mode excitation
voltage is very high despite having a low differential mode voltage.

It isn't that difficult, draw it on paper or model it.

Definitely! And thanks everyone for the sites and insights! 8^)

I'm going to build one of these. And I have one more question.

Of what importance is the solder vs one continuous length argument? I can get long lengths of copper tubing, and fashion a home made bender to work it into a circular shape, but a soldered octoloop would be simpler and quicker to construct. Does the resistance of the solder joints really make that much difference?

What you would want is the antenna system to have the same terminal voltage on each terminal, along with equal and exactly opposite currents in the feedline.

Using a large ground system insures one wire of the balanced line has a very low common mode impedance, while the other feeds the antenna that can (on some bands) have several hundred ohms or more. Unbalance would occur because of that, unless you used a choke balun at the feedpoint.

>elements relationship to ground.) Next added an additional three

Go back to a J-pole, a Zepp antenna, or even a dipole.

Would a dipole fed with a balanced line be more balanced if we made one half have four wires on one side instead of one in-line wire the same length as the wire on the opposite side?

What is better balanced, an Inverted Vee Dipole with one wire on each leg or an Inverted Vee dipole with four fanned out wires on one leg and a single wire on the other?

What about a J-pole? Is it better balanced when we install a large groundplane below the 1/2 wl element base and feed it with a balanced feed below that point?

Verticals with large ground systems are almost perfectly UNbalanced antennas. Verticals with small ground systems (like 30 feet up and 30 feet out on one radial) are much better balanced!

I'd certainly use a large ground system with a coax-fed vertical, but if I used open wire I'd want a balanced antenna...even if it was a bit bent! The better the ground system, the more the open wire line would

radiate for a given common mode impedance of open wire line.

I hope you see what I mean.

Okay let me ask one.

Which is better blanced fed point a ground-plane where the monopole's
length and the radials length are the same or one where the radials
are only ï¿½ the length of the antenna element?

My apologies, the statement may be a bit confusing.

As far as I know, an antenna does not carry "common mode currents"
and the claim was that wiring could pick up common mode currents from
the antenna.

It is certainy true that house wiring can "generate" common mode
currents from the energy in the signal generated by the antenna.

You are right about the resistive losses that should be avoided.
I wouldn't worry too much about the exact effectiveness of the loop. I use a MFJ 1788 and on 40 meters it must have an effectiveness of about 25% which is only 1 s-unit less signal than a 100 % effective full size dipole antenna... And it's difficult as well to get a 100 % effective 40 Meterband dipole antenna as it requires at least a distance of 20 meters over the ground in free space. The resistive losses in dipole antenna's and in the traps and in baluns isn't making them any better either. And because the magnetic loop is very quiet it can hear things that are lost in the noise on other type antenna's. I get very strong signals (s9++) on my loop antenna's despite all the resistive losses and low effectiveness on the lower bands.

For transmitting it's slightly an other story. Because the maximum RF power (about 100 Watts) one can use in an average Magnetic loop. The effective radiated power on my MFJ loop on 40 Meter is only about 25 Watts when using 100 Watt output from the rig . That isn't too much to compete with QRO stations on this crowded band. But using my old AEA isoloop for 10-20 meter I can make intercontinental SSB QSO's from my country here in Europe, using 40-100 Watts from the rig. The effectiveness of the Isoloop is about 50% on 20 meter (half an s-unit under a full size dipole) so it's no problem to DX eventhough the antenna isn't perfect.

I even used the MFJ loop with my FT-817 QRP set with two and a half Watts and made several contact inside Europe on 20 meter. I use my loops in vertical position which works best here because I'm close to the ground on the 1st floor of an apartment building.

I have seen many beautiful designs of loops. One that inspired me when it comes to designing a high voltage capacitor was the following site (Acrobat reader required):

www.elecraft.com/TechNotes/loop_ant/wd8puoloop.pdf

Everything needed for the capacitor is available in the hardware store. I have no idea about the resistive losses in this kind of capacitor.

Any comment on this copper-tube design is welcome. Does anyone here has experience with this kind of capacitor?

As follows: The differential current is 1/2 the difference of the current on the outside of the inner conductor and the inside of the outer conductor. It is not the same as one of the constituent currents.

That is, if the two currents are I1 and I2, the differential current is 1/2 (I1 - I2). This is clearly not equal to I1 -- unless I2 is zero, which it's not.

That sounds pretty complicated. But it's really pretty simple.

Richard Harrison wrote:
> Roy Lewallen wrote:

> Where is the return path of the current on the outside of the shield?

The current on the outside of the shield flows between the inside of the shield (at the antenna) to ground.

> Answer, there is none unless there is an unbalanced antenna connected to
> the coax even if the coax itself makes part of the antenna.

This can, and does, happen when the coax is connected to a so-called balanced antenna like a dipole.

> Since all power inside the coax is differential and this power includes
> that supplied to the common-mode, the total power taken from the coax
> can`t change and not change current inside the coax.

When a dipole is fed with coax, the current on the inside of the shield splits between two paths. One is the dipole half it's connected to. The other is the path along the outside of the coax shield to ground. The current can be steered from one path to the other in any ratio without affecting the vector sum, which is the current on the inside of the shield.

> Another analogy: A river splits into two outlets flowing into the sea.
> One outlet can`t be blocked without affecting current in the mainstream
> and the remaining outlet.
>
> Common-mode current isn`t blocked or altered without affecting
> differential-mode current in a given system.

Sorry, this simply isn't true. See my previous paragraph.

> Concocting a system to change the common-mode without changing the
> differential-mode would be an oddity.

A balun can be such a system. When a current balun (common mode choke) is placed on the outside of the coax, the differential impedance can increase, decrease, or remain the same. It depends on the impedances of the two paths the current on the inside of the shield can take.

Please see my response to Richard Harrison. 1/2 (I1 - I2) is not I1.

One side of the dipole is part of the differential load. It's also part
of the common mode load.

Mis-information indeed. A little manipulation of the equations in
Reference Data for Radio Engineers or any other transmission line text
gives, for a lossless line:

V2 = V1 / (cos(theta) + j (Z0/ZL * sin(theta)))

where

V2 is the voltage at the load end of the line
V1 is the voltage at the input end of the line
Z0 is the line's characteristic impedance
ZL is the load impedance
theta is the electrical length of the line

So let's take an example, say a 100 ohm quarter wave line driven with
100 volts at the input and terminated with 10,000 volts.

V2 = 100 / (0 + j (Z0/ZL) * 1) = -j10,000 volts

The magnitude of this is 10,000 volts, or 100 times the input voltage.
Or did I do the arithmetic wrong?

Does the resistance of the solder
> joints really make that much difference?
==========
Only to old wives.

Soldered-together copper pipes obey ohms law just like any other resistances
in series.

A few little micro-ohms in series with 10's of milliohms don't make much
difference.

With this type of antenna, the better the ground system,
the better the performance. The 'best' way to connect the
braid to the ground system is by soldering it.
(the first sentence means more than the second sentence, but
both are true.)

This thread has moved a long way from its origins. I'd like to
contribute to that by picking up just one aspect of what Roy Lewallen
wrote:

>> Where is the return path of the current on the outside of the
>>shield?
>
>The current on the outside of the shield flows between the inside of
>the shield (at the antenna) to ground.
>

>
>This can, and does, happen when the coax is connected to a so-called
>balanced antenna like a dipole.
>

Yes, indeed - it can, does and <always will> happen. Even in an
idealized symmetrical environment, a "balanced" dipole automatically
becomes UNbalanced whenever a coax feedline is connected directly to it.
That is because, contrary to some books, a so-called "symmetrical"
coax-fed dipole is <never> "balanced" - and never can be.

Why? Because it's fundamentally, irretrievably asymmetrical! One leg of
the dipole is connected only to one conductor (coax inner) but the other
leg is connected to two - the inside and outside of the shield, which
operate as two independent conductors because of the skin effect.

Immediately you connect the coax, current flows on to the outside of the
shield and it becomes part of the radiating system - just as if you'd
connected another wire to that side of the feedpoint.

Need more detailed proof? Imagine this:

Step 1: A perfectly symmetrical horizontal dipole above horizontal,
flat, infinite ground, and surrounded by a perfectly symmetrical
environment. Center-feed it by a tiny battery-powered transmitter
hanging at the feedpoint. Is this system balanced? Yes, because it's
perfectly symmetrical.

Step 2: Attach a wire to one terminal of the transmitter, and trail it
away towards ground. Is this system balanced? Of course not, because it
isn't symmetrical. Even if you run the wire away at right-angles to the
antenna, the system still isn't symmetrical, because one terminal of the
transmitter has two wires attached, while the other terminal has only
one... an asymmetry which is impossible to ignore.

Step 3: Replace the new wire with coax, following the same route. Attach only the shield to the antenna, where the wire was attached in Step 2. Is this system balanced? No, it's as asymmetrical and unbalanced as before.

Step 4: Remove the transmitter and connect the center conductor of the coax to the free terminal of the antenna. (The outer shield of the coax is already connected to the other antenna terminal.) Re-connect the transmitter at the far end of the coax. Now this is the system that some books - and readers - claim is "balanced". But is it? No - it's the same as Steps 2 or 3 which we just agreed were unbalanced. All we did was move the RF source.

It follows that <any> coax-fed antenna can never be truly balanced. Some outer-shield current will <always> flow - it can never be truly zero. In some situations this current may be so small that you can ignore it ("I don't need no stinking balun"). In other situations it's large enough to cause problems, so you need to reduce it with a feedline choke. But in all situations, <some> outer-shield current is <always> there.

This myth of the "balanced coax-fed dipole" is just like the story of the Emperor's New Clothes. I confess to getting sucked into the myth for a long time, and wish I could call back some of the things I've written in years past. But not any more.

Another part of this prevalent myth is that in a "balanced coax-fed dipole" the outer-shield current somehow "wants" to be zero, and will tend towards zero if you let it. But that's not true either - the current always "wants" to be finite, and flowing.

> impedance and voltage and that is what Richard responded to??

Why are you answering a question with a question, Tom? Last time I checked,
I = E/Z. Are you saying Ohm was wrong? Current *IS* the relationship
between "impedance and voltage".

> I don't think currents have ever been in dispute, nor have I mentioned
> them. Why dredge them up??

Current is part of the "conditions" that you said were not related.
Current is related to "impedance and voltage", is it not?

> The voltage and impedances can have any relationship (which to me is
> the same as saying they are "unrelated").

You contradict yourself. If they can have any *relationship*, then they
cannot possibly be *unrelated*, now can they? You admit they have some
relationship and then you say they are unrelated. You simply cannot have
it both ways. If they can have any relationship, then they are related
through that relationship, whatever it might be. Your ignorance of the
exact relationship doesn't change reality to make them unrelated.

Crack open a dictionary, Tom. You obviously do not know the definition
of "related". The relationship that voltage has to impedance *is* current.
Two resistors chosen at random can have any relationship. But when you
put them in the same circuit, they become related through Ohm's law
and Kirchhoff's law. Once chosen, the relationship of their ratio is fixed,
i.e. related. That fact has to be obvious to you yet you refuse to give up
on your false statements.

What is the difference between saying 1000 times that a 75m Isotron will
beat a 75m dipole and saying 1000 times that voltage and impedance are
unrelated? You are doing exactly what you condemn others for doing.

100 mohms 1%?
Please quote your source. I have never heard of this and would like to see where this spec came from since every loop is different, I can't see how this can generalize into a 1% loss in efficiency per every 100mohms of resistance. Now just because I never heard of it doen't mean it's not true but I would find it an interesting read to discover how they came up with this measurement.

Since the common mode velocity factor and impedance of the
transmission line is not directly related to the differential mode
impedance, what you observed can and certainly does change in OTHER
well-balanced tunerless systems.

It is a **mistake** to assume that selecting a low feed impedance
means common mode problems are minimized, or that a choke balun has an
"easier time" doing its job.

That is my only point.

>I can't speak for Richard, but I would be satisfied with "often unpredictable"
>or "usually unknown". I thought we had settled this topic a week ago.

Taking threads totally off topic with *incorrect* examples of how they
are "related" doesn't help anything or anyone. very often in technical
language, some liberty is b given from Websters. The most important
point is that people trying to learn get a feel for what is happening
in the system, not in Websters Dictionary.

That is where you are wrong Richard. The differential mode voltage is not directly related to the common mode voltage exciting the line, and thinking it is will get you in trouble in nearly every real-world antenna system used.

Model a half-wave antenna with a source, and hang a vertical 1/4 wl wire from that antenna as you would with a feedline to model common mode currents. Place a very high impedance load or a source set to zero current in series with that wire. The source feeding the half-wave wire would be the differential mode impedance of the antenna and would give you the differential mode voltage. The wiring hanging and the zero-current source (or nearly infinite load) in series with it would represent the balun and the ultimate voltage it must hold off to do its job.

You'll see at any point where the "feedline" and differential source is offset the voltage ratios of the two are NOT equal or even similar. The balun might be required to hold off several times the differential voltage.

This can be the case even with a perfectly symmetrical feed location. As a matter of fact, intentionally trying to obtain a perfectly symmetrical feed location or a low feedpoint impedance can make many systems worse.

Hence my choice of the words the common mode voltages or impedances of a system are not related to the differential mode. You seem to think they are directly tied together, as do many other people, and that will get you into trouble all the time.

Especially when you are using that incorrect idea or concept to be critical of someone else in public.

It has been previously reported here on r.r.a.a that the field structure of coax forces the current on the outside of the inner conductor and the current on the inside of the outer conductor to be equal in magnitude and opposite in phase. Was that a false statement?

It has been previously reported here on r.r.a.a that when the inner conductor of coax is shorted to the outer conductor of coax and the resulting cable is used for RF grounding, that the inner conductor carries virtually none of the RF because of skin effect. Was that a false statement?

I don't know, but it would be easy to find out in a model or by
building one.

I'm sure best balance for open wire would occur when the multiple
radials are shorter than the radiator. If the radiator was a thin 1/2
wl long radiator, best balance would occur with almost no ground
screen at the end of the feeders second wire. Like a Zepp or J-pole
feed.

The better the ground system, the more the system "wants" to be fed by
coax.

As a matter of fact, coax feeding a groundplane can radiate a
considerable amount if the ground system is only four or less radials,
and there is no balun at the feedpoint!!! Less than perfect grounds on
verticals fed with coax are one of the things that causes people to
think altering the feedline length of a 50 ohm cable changes 50 ohm
referenced SWR.

Most antennas are nether pefectly balanced or perfectly unbalanced,
and many are not even close to what we think.

The question was aimed at Dan based on something Dan said.
I just couldn't resist pointing out a contradiction. If common
mode conditions were as unrelated as Tom says, he couldn't
possibly know very much about them.

>[snip]

Tom,

I went back and modeled the antenna using the dimensions as described,
with four evenly space radials the same length as the monopole and
feeding it with a parallel transmission line with 1" spacing. Then
checked the transmission line currents at the antenna's feed point for
20 and 15 meter operation. I used heavy segmentation and the only
thing I changed was the frequency.

On 20-meters the current magnitudes were within about 3ï¿½% and the
phase differential at 178ï¿½ - really not too bad.

However at 15 meters the current magnitudes varied by 43% and the
phase differential as only 82ï¿½ï¿½. Ugh, lousy!

Neat thing about modeling; you can check things out if you take the
time to do it.

So I was in error. Making the radial elements the same length as the
monopole will not necessary produce a more "balanced" feed point for
ladder line.

Oh well, if you're going to screw up you might as well do it front of
God and everybody.

>joints really make that much difference?

You can certainly obtain very low resistance solder joints compared to
the resistance of the antenna and capacitor, so I would not worry much
about soldering as long as the joints are in LARGE tubing like one
inch or larger copper.

The feed system is also not critical, and does not need to be fancy or
have any efforts made to use fancy "baluns". It can just be a simple
small loop of wire. I would avoid gamma matches or any other dircect
feed, however!

The single most critical part is the capacitor, and how you make
connections to the capacitor. I've watched efficiency change from a
few percent to 50% or more just by changing from a flat-plate
capacitor with a teflon dielectric to an air dielectric cap that is
"boxy" with welded stator plate connections.

Make the loop as large as possible, and it saves you headaches. Do NOT
expect to actually get the efficiencies most articles or books claim.
many of them just don't realize how much ESR the tuning capacitor has.
Even a very inefficient antenna can still be very useful and fun!

I'd still use the least numer of soldered connections, but the
resistance of wide surface area tight fitting well-soldered
connections like between clean tight-fitted large copper tubing is
very low compared to the rest of the system.

The capacitor and connections to the capacitor almost always would
dominate the system loss resistances by a large margin, making effects
of soldering unnoticable if done properly.

What we really must avoid at all costs are pressure connections of any
type that carry current, unless it is a multilayer high pressure
bolted connection. We also should avoid long large-area capacitors,
and use a part that is a "boxey" and compact as possible.

I have never said it doesn't, Tom. You are the one who has been on the rail, not I. You are the one who has been using words that exclude any other possibilities, e.g. "NOT related", "always", and "never". For your absolute railing statements, all it takes is one example to prove that you are wrong. Please get off the rail and the problem will disappear.

> It is a **mistake** to assume that selecting a low feed impedance

> That is my only point.

If that is your only point, then you have certainly been engaging in hyperbole with your absolute, all-encompassing railing statements. Is it too much to ask for you to include a "usually" or "often" or "sometimes" in your otherwise absolute statements? "NOT related" means never a relationship of any kind and is an absolutely ridiculous thing to say about conditions that share a common power source.

> >I can't speak for Richard, but I would be satisfied with "often unpredictable"
> >or "usually unknown". I thought we had settled this topic a week ago.

> point is that people trying to learn get a feel for what is happening
> in the system, not in Websters Dictionary.

I am amazed at your capacities for mealy-mouthing, Tom. You simply cannot willy-nilly invent new definitions for words like "unrelated". You contradict yourself when you admit that something can have "any relationship" yet is still "unrelated". "Unrelated" is absolutely NO relationship. You have wasted an immense amount of energy defending an indefensible position apparently for the purpose of covering up a mistake as simple as not knowing what the definition of "unrelated" is. Trying to twist definitions into something they are not is simply foolish. Without common definitions for words, communications is impossible. Is that what you really want?

From studies of rhombic antennas of long ago, I add one item to Tom's
good summery:

The effective bandwidth of a rhombic is about 2:1. They will accept
power with low VSWR (if designed with any care at all) over a much wider
bandwidth.

As Tom has said, in almost all settings, better choices exist.

One rail is "not related". The other rail is "directly tied together".
The gigantic middle ground is "indirectly tied together" or "related
in an unpredictable manner". Both rails are wrong, as rails usually are.

Your logical diversion is obvious. I have said my motorcycle is not
black. You turn around and accuse me of saying my motorcycle is white.
Old trick, doesn't work.

Have you, by chance, thought about changing to a good vertical? Yes I know the argument will start about radials and all that, but a good Cushcraft or Titan or something like that could work wonders for a person caught like you with their grounds down!

Sometimes you can't fix the problem! So you fix the symptom. And then you find something wonderful you had been missing all along! Other times you don't, but the deal you don't investigate is the one you lose!

Roy Lewallen wrote:
"A balun can be such a system. When a current balun (common mode choke) is placed on the outside of the coax, the differential impedance can increase, decrease, or remain the same."

True. That is because the common-mode is related to the differential-mode by imbalance in the system. When common-mode impedance is increased by adding inductance to the coax exterior, the coax exterior takes less energy from the coax`s interior. When common-mode impedance is reduced by adding inductance to the coax exterior, the coax takes more energy from the coax interior. These interactions occur because the common-mode is related to the differential mode. When adding inductance to the coax exterior has no effect on the differential-mode, system balance has removed coupling and no common-mode current exists on the coax exterior.

The complex mutual impedance between the differential-mode and the common-mode can be measured, making behavior of the system predictable. Or, you can cut and try.

Best regards, Richard Harrison, KB5WZI

Roy Lewallen wrote:
"So let`s take an example, say a 100 ohm quarter wave line driven with 100 volts at the input and terminated with 10,000 volts."

Can`t argue with that!

If you have a zero-impedance 100V source, at the end of a 1/4-wave line segment, you have a virtual open-circuit at the 10,000-volt application point. A shorted 1/4-wave stub is also called a "metallic insulator". The 100V source is only 1% of the 10,000V so is inconsequential. So, at the 10,000V end of the stub, the voltage is approximately 10,000V.

What`s the price of eggs in China today?

Best regards, Richard Harrison, KB5WZI

Imagine a coax with a resistor connected across the far end. The current will return via the inner surface of the shield, regardless of the impedance of the outer surface of the shield.

Reason: Maxwell's equation curl H = J (neglect the dE/dt as irrelevant within the shield). This law says in a roundabout way that in order for the H field to be zero within the shield the magnetic flux linkages at the inner surface due to the center wire and the magnetic flux linkages due to the return current on the inner surface must be equal and in opposite directions. See also Terman 1955 page 22, which states (equivalently) that "the general principle is that current flows where it is encircled by the smallest number of flux lines". This can be true only if the current returns via the inner surface.

The idea that the division of current is according to the impedance of the outside surface of the braid, is basically and fundamentally incorrect. There is more than just Ohm's law involved here. Intuitions fail in this situation.

The current on the outside is due entirely to electromagnetic coupling from the antenna elements.

Furthermore, another Maxwell equation says that the divergence of B = zero, which leads to the conclusion that current flows only in closed paths. This means that the common mode current that flows into a ground connection must find its

way back to the antenna by some means, usually by electromagnetic induction (transformer action). If the antenna is highly isolated from "ground", as in space, there is no common mode current into a "ground" connection, and only the generator platform, transmission line and antenna are the closed path for common mode current.

The example above referred to a resistor across the end of the coax. The situation for the dipole is no different, if electromagnetic coupling from dipole elements to coax outer surface is treated separately (superposition applies).

That is pretty much what I was thinking. So for at least my first loop,
I'll go the soldered route. Now for the decision on the Capacitor.

A posting from Tom, W8JI dated Sun,Jul 7,2002, 2:36am, arrived on my screen a few minutes ago. Mysterious cyber processing!

Tom says: "---someone stuck a balun at a point with low differential impedance, and where everyone concluded the balun should have an effect or be effective."

The feedline acting as an unbalanced antenna has a feedpoint impedance. It has a radiation-resistance and usually reactance too. It takes most power when matched to its source. Adding the inductance of a common-mode choke balun could offset some of the capacitive reactance of a too-short length for increased current input and increased radiation. Indiscriminate application of a choke balun is no panacea for feedline radiation.

If the characteristics of an antenna feedline are unknown as a radiator, you can measure or experiment to determine the action required for reduced feedline radiation.

It is not likely possible to explain the interactions between antennas and feedlines satisfactorily in one sentence. You might start by saying they are usually detrimentally coupled.

Best regards, Richard Harrison, KB5WZI

Suppose we loop the coax back so the load can be located close to the transmitter ground. Suppose our load is a Z0 resistor that is off-center tapped to ground. "Electromagnetic coupling" does cover a lot of bases but in this new example, wouldn't there be some conducted common mode currents on the outside because the Z0 load resistor is not floating with respect to ground?

Hmmmm,

I am curious how this works out in practice.

In many other messages it has been said that once measurements are made of two different systems or components or other entities then we can say the entities are "related", even if we do not fully understand the nature of the correlation or any possible cause-effect behavior.

Fair enough; I won't argue the semantic distinctions.

The question becomes, however, can ANY set of measurable systems EVER be "unrelated"?

Are there any examples of measurable systems that are unrelated using the all-inclusive definition above?

If not, it seems that the absolutism in this thread is useful only for philosophers, not technologists.

Sure, I would agree that the primary (measurable) common mode currents in my antenna system during transmit are unrelated to the primary (measurable) differential mode currents in your antenna system during transmit assuming you are in the '4' call area and I am in the '5' call area. I can have common mode currents while you are transmitting or not transmitting. My primary (measurable) common mode currents occur *only* while I am transmitting. To try to maintain that common mode conditions are unrelated to differential mode conditions during transmit from a common power source is ridiculous and getting more ridiculous all the time.

There is a one-to-one correspondence between the movement of the meter needle on my differential power meter and the movement of the meter needle on my common mode current detector. Both of them correspond to key-down during CW operation. To assert that they are unrelated after observing the relationship on the meters would be an outright lie.

(neglect the dE/dt as irrelevant within the shield).

Yes, and it doesn`t hurt that the load resistor is a balanced load.
There may be an explanation for those not properly introduced to
Maxwell.

The current on the outside of the coax needs a complete return path. It
isn`t available in the coax differential mode. It also isn`t available
in balanced excitation fields from the antenna. There must be an
imbalance in the displacement current from the antenna, in which the
coax exterior is likely complicit, to produce a return path for the
common-mode current so there is a complete circuit and the feedline can
radiate.

==============================

Wiping capacitor contacts of good design don't cause much loss either.

There are two rotating disks, one mounted near each end of the rotor shaft.
Bearing on each disk are two, fixed, short, fairly strong leaf springs.
There can be 12 or more sliding contacts all in parallel, 6 near each end of
the shaft. The two sets of spring forces tending to move the shaft along its
axis balance each other out. But friction by leaf springs on the disks
require a stronger drive motor.

Tom, W8JI wrote:
"The differential mode voltage is not directly related to the common mode voltage exciting the line---."

Mutually coupled circuits are just that. Perturb one circuit and the perturbation is sensed in the other circuit.
The circuits we have discussed are mutually coupled circuits. The only exception is at perfect balance when coupling is zero. In this unique instance there is no signal in one of the circuits to discuss anyway. We are discussing single signal source arrangements.

In the arrangements discussed, the common-mode signal is a product of the differential mode signal. When changing one voltage causes another to change, they are related by most reasonable definitions.

Tom,
Instead of struggling with the losses created by the capacitor,
joints e.t.c, why not concentrate on increasing the impedance
of the antenna so that connection losses become some what
inconsequential ? It appears to me that the low impedance of
the loop antenna which creates low efficiencies, overcome all the
advantages touted by the mutiband atributes of variable frequency.
If one modifies the loop by placing at the center of a dipole,
or its equivalent, the antenna impedances rise and with it higher
efficiences without the the losses imposed by the imposition of

'connection' losses.

I have provided but one example where changing the 'focus' removes the majority of the loop and capacitor problems (please correct me if I am wrong) and I am sure that the knowledgable could provide other examples, fractal (loaded)shaped dipole, if they would only open their minds and look away from the 'basic' design of the loop and incorporate the capacitor driven variable frequences that it offers to a more efficient and user friendly antenna.

I have the feeling that the original claims of high efficiencies and its subsequent 'debunking' have locked most hams to the pursuit of removing losses of the original design to validate original claims, instead of building on it's attributes by increasing the antennas impedance.

Source record: 138656

Hi Matt
I have recently put up the "Lightning Bolt" 5 band Quad. I elected to use the supplied balun for now and keep it simple until I got it all working good. Well it has a 1.5 to 1, or less, match on all the 5 bands(10,12,15,17,and 20). It covers all the band on each within the 2 to 1 SWR points, except for 10 meters. 10 meters has so much band to cover it does not cover all of it. I have mine adjusted so it covers 28.000 to 28.6 something within the 2 to 1 SWR curve. It performance is absolutely fantastic! I really don't see how seperate feed lines could make a big difference. I can't ask for this beam to work any better. It's quieter than my dipoles by a significant amount. It's quiet nature makes it possible to copy weak signal that are lost in the noise on my dipoles, and copy them well. Most of the time an S-3 signal on the dipole is S-9, or more, on the quad. Not always, but there is not any antenna that will always be best. Honestly though, the quad is always equal to or most of the time much better than the dipole. Not mentioning the noise difference. So with all this taken into account, and doing a little research on the web, I see no reason to go to the extra expense and trouble to make 1/4 wave matching sections for each band, and putting up the needed remote antenna switch. From a purists point of view it would be better. From a realistic point of view, in my opinion it won't make enough difference to matter. If, and this is a big if, it gained you 2 or 3 dB of effective radiated power, no one would be able to see much difference on the receive end. As 3 dB is 1/2 an S unit. And propagation can make that a mute point. If the bands all give a good swr match over all, or most of the band with good performance, then whats to be gained to make it worth while. Plus you'll have more stuff up in the air to maintain. If you'd like I can give you a web site to look at some info on the differences in a balun fed quad compared to one with 1/4 wave matching sections. I'd give it to you now. but I will have to look it up in my files . Hope this helps. I don't think this antenna will dissapoint you and I don't think it will dissapoint you fed with the balun and one feed line.

If I1 is the current on the outside of the inner conductor and I2 is the
current on the inside of the outer conductor, then doesn't I1 equal I2 in
magnitude and opposite in phase so that differential current equals I1?

Yes. They're equal in value, but they're not the same current. I1 is the current on the outside of the inner conductor. The differential current is composed of both I1 and I2.

It wasn't intuition I was applying there, but Kirchhoff's current law:
that the algebraic sum of currents flowing into and out of a given point
in a circuit is zero. That law of physics is based on simple counting of
electrons (aka conservation of charge) and it cannot be arbitrarily set
aside.

I am also assuming that the inner and outer surfaces of the shield act
as independent conductors, thanks to the skin effect - but I have very
good support for that [1].

Ohm's law will then dictate how the currents divide.

>The current on the outside is due entirely to electromagnetic coupling
>from the antenna elements.
>
I don't have the background to try conclusions with Bill about EM theory, but I have total confidence that a correct and complete application of Maxwell's equations to this problem will show that both of our approaches are correct.

The currents created by electromagnetic coupling between the antenna elements and to the outer surface of the coax (acting as an independent conductor) will in turn create certain current conditions at the feedpoint. If Bill's EM approach is worked out in detail, it will provide the following information:

1. The currents on the center conductor and the inside of the coax shield are equal and opposite (as Bill said).

2. The current distributions on the two halves of the dipole are known in full numerical detail, and they are not quite equal.

3. There will be a small current on the outer of the coax shield, and again its distribution along the length of the feedline is known in full numerical detail.

4. The three currents at the top of the shield (where the inner surface, the outer surface and one side of the dipole all join) will sum to zero, within the limits of error in calculating each current.

But I can also approach the problem a different way:

1. Bill and Maxwell tell me that the currents on the center conductor and the inside of the coax shield will be equal and opposite. I can take this as a given.

2. The inner and outer surfaces of the shield act as independent conductors, thanks to the skin effect [1]. I'll assume that the shield is conductive enough and thick enough to allow negligible interaction between the two current sheets.

3. Because the system is not symmetrical (one side of the dipole also has the outer of the shield connected to it) the currents on the antenna arms cannot be exactly equal.

4. Kirchhoff's law dictates that three currents at the top of the shield (where the inner surface, the outer surface and one side of the dipole all join) must sum exactly to zero. No approximation, no room for argument.

5. Therefore a small current will be launched from the feedpoint onto the outer of the shield. I don't know how large that current will be, but the lack of symmetry proves that it must be non-zero.

Bill's approach offers much more information, and deeper numerical insights, but I choose a simpler approach that gives me a qualitative picture of what's happening at the feedpoint. It doesn't tell me

anything about the current distributions farther away from the feedpoint, but that wasn't part of the original question.

To take another example, Bill said:
>Imagine a coax with a resistor connected across the far end. The
>current will return via the inner surface of the shield, regardless of
>the impedance of the outer surface of the shield.
>
My approach would be that since the currents on the center conductor and the inside of the coax shield are equal and opposite, Kirchhoff's law tells me that no current is available to flow on the outer surface. We reach the same conclusion by different routes. Both approaches are valid.

>Furthermore, another Maxwell equation says that the divergence of B =
>zero, which leads to the conclusion that current flows only in closed
>paths. This means that the common mode current that flows into a ground
>connection must find its way back to the antenna by some means, usually
>by electromagnetic induction (transformer action).

The requirement for every current to have its return path is certainly true, but I don't see how that is a counter-argument. It does not contradict the validity of Kirchhoff's and/or Ohms law at any point in the system.

>If the antenna is highly isolated from "ground", as in space, there is
>no common mode current into a "ground" connection, and only the
>generator platform, transmission line and antenna are the closed path
>for common mode current.
>
Not true - a ground is not necessary in order to create a common-mode current at the feedpoint. In any practical system, the feedline length is a significant fraction of a wavelength, so the outer surface radiates and has its own current distribution along its length.

If you take the systems I described in Steps 1-4 in the previous posting and move them away from ground and into free space, as a "T" shape with the battery-powered transmitter at the far end of the coax, the general behavior is quite similar. Even when the coax runs away from the center-fed dipole exactly at right-angles, the system is still not symmetrical at the feedpoint, so there will be some current launched onto the outer surface of the coax.

Given this situation at the feedpoint, and the dimensions and thicknesses of the three conductors, the current distributions on all three can be worked out in the usual way. Grounding the bottom end of the feedline shield (or providing a partial ground by capacitance) will of course alter the common-mode current at the feedpoint, but it won't alter the fundamental conclusion that this current has to be non-zero due to the asymmetry.

To sum up, I stand by what I said:

>>... the inside and outside of the shield ... operate as two
>>independent conductors because of the skin effect.
>>
>> Immediately you connect the coax, current flows on to the outside of
>>the shield and it becomes part of the radiating system - just as if
>>you'd connected another wire to that side of the feedpoint.
>

[1] This topic has been coming around again and again, for a long time. Some years ago I sent Bill a copy of some pages from a textbook containing a very neat derivation of the skin effect. Unlike most textbook proofs, it doesn't make any assumptions about the type of circuit or conductor involved. It simply assumes an RF current flowing over a conducting surface, no reason given or required. It then uses Faraday's law and Ampere's theorem (both of which were unified by Maxwell's equations) to prove that the skin effect will happen, and to derive all the relevant equations.

Come to think, those scanned pages are still on my site from a previous round of this same discussion, at:
www.ifwtech.co.uk/g3sek/misc/skin.htm

Note again that it is not necessary to know <why> the RF current is flowing. I take that to mean that it is valid to use the existence of skin effect as a starting-point for explaining circuit behavior - because if there are RF currents, there will always be a skin effect. That means opposite surfaces of the same conductor will behave as if they are independent, provided only that the material is conductive enough and thick enough to allow negligible interaction between the different current sheets.

The only one I've ever personally worked with is the Butternut 80-upwards creature. I'm a low band enthusist and only use full sized separate stalks for 80 and 40 at the fixed site. I did help set up one for a friend years ago and we used one for Field Day about five years ago. It worked very well. Friends who have used both that brand and also the Gap stuff for no-room basis yards have been pleased. One local fellow WA5OMD here is up to 300+ confirmed all bands with a GAP that's elevated with a base up about 24 feet. That's a decent testimonial I would think.

W5TC, ex-ARRL Director Tom Comstock here in College Station, had a Hy-Gain self-supporting 18AVQ in his back yard plus only a good tribander. He's the only one I ever knew who had a collection of all the cards from all the deleted countries! Must be a reason this stuff works, eh?

I held a complete solid week's schedules for research purposes on gray line between my W5WQN site and HZ0ZAA a number of years back on 40 CW between my 4 square and his R4 up about 30 feet to prove a point or two. Absolute success every time, every day that week, and only 100 watts at his end right on schedule. Others here can offer you actual data on an as-normally used basis for these things. But I can't give you an experience-line on them based on months or years worth of use as compared with the usual low dipoles etc.

Frankly, take a single band, say 40 or 30. Throw up a wire element job from a tree if you can just to play with it if you can. Won't cost you much of anything that way. If you are pleased, you should have your answer and will have likely had a lot of fun doing it. You can hint that, "If it works, I may be able to reduce this whole mess to xxxx!"

;)

It's sorta like the recent Del Taco commercials! Just think outside the box!

Mike, for a fairly complete analysis of performance of magloops download program MAGLOOP4 from website below.

An similar earlier program RJELOOP1, still available, computes both radiation resistance and conductor HF resistance.

Both programs cover loop shapes from triangular to circular.

Between them they should overide the old-wives waffle which is going on in this and other threads.

Q of the tuning capacitor is much greater than Q of the loop conductor itself and can be ignored in comparison. That should be obvious by considering the lengths and surface areas of these two principal components.

The loss resistances are so small and the Q's are so large of these components they are well beyond direct measurents. They can be accurately obtained only by calculations from basic electrical principles.

In practice, of course, 1 or 2 dB don't matter very much. Not worth having a riot about!

Download in a few seconds. No unzipping inconvenience involved. Run immediately. User-friendly.

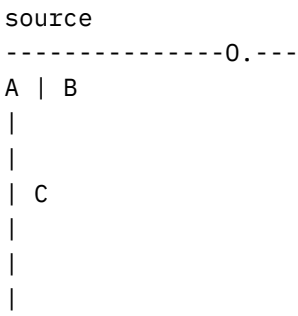
Ian's recent posting prompts me to correct a statement I made earlier, that the current flowing down the outside of the coax is flowing to ground. As Ian pointed out, a ground connection isn't at all necessary. Imagine an antenna in free space made by starting with a dipole, then adding a second quarter wave wire. I try to avoid ASCII art, but need something to describe this. You'll need a fixed-width font to see this correctly:



I've just added a third quarter wave wire C to the dipole made from A and B. At the feedpoint, both wires B and C present a relatively low impedance to current, so current flows in both of them. For both wires, the current is maximum at the feedpoint, and drops to zero at the ends. No connections to ground or anything else are necessary. This is the situation you'd have if you hung a dipole fed with a quarter wave coax line high above the ground, and dangled a battery-powered transmitter from the bottom end of the quarter wave line. Wire C represents the outside of the coax. This situation is easy to model with EZNEC or other program. Just like the current on wire B, the current on wire C is generating a field which radiates, so we can continue driving current and power into the wire without the necessity of it exiting anywhere except in the form of radiation.

Roy Lewallen wrote:
"Sorry, this simply isn`t true. See my previous paragraph."
The paragraph:
"When a dipole is fed with coax, the current on the inside of the shield splits between two paths. One is the dipole half that it is connected to. The other is the path along the outside of the coax shield to ground. The current can be steered in any ratio without affecting the vector sum which is the current on the inside of the shield."

The vector sum is a limited resource. Steer more or less current to either path and current in the other path changes. Since one path is the differential-mode load and the other path is the common-mode these modes are related by this teeter-totter that Roy has described.

My analogy that Roy has called untrue, said that if you blocked one of two river outlets to the sea, current in the mainstream and the unblocked outlet would be affected. Almost all analogies are faulty but some are useful in spite of their faults.

One reason the vector sum is a limited resource, but not necessarily a constant sum, is that the coax will deliver maximum power only into a conjugate match. If you have such a match, changing the impedance of either pathload changes their sum, and the amount of the power delivered as a "vector sum". Even if you don`t have a match, it changes whatever match existed.

My characterization was true enough. Roy`s response is more testimony, although unintended, that the differential and common modes are truly related.

Best regards, Richard Harrison, KB5WZI

Roy Lewallen wrote:
"As Ian pointed out, a ground connection isn`t necessary."

The radiating coax transmission line differs from an upside-down ground-plane. The currents at the upside-down "base" of the radiating coax are flowing toward the "base" on one "radial" and away from the "base" on another "radial". In the ground-plane, currents all flow toward or away from the base in-step on all radials.

Imbalance in the coax upside-down ground-plane "radials" enables its radiation. The more it mimics a true ground-plane, the better it radiates.

CAM, W5DXP wrote:
"Aren`t I1 and I2 in series?"

There is an arithmetic principle as Cecil knows, that says that things equal to the same thing are equal to each other. In the case of currents in the two wires of a transmission line, the line`s behavior makes the current identical in magnitude.

So, it`s fair enough to sum the absolute values of I1 and I2 then divide by two. Their average is also identical to the current in either wire.

This was just a sideshow conducted at the main circus.

This doesn't make sense to me. But I see it's not possible for me to communicate the fact that the differential and common mode currents are simply mathematical derivations of individual currents flowing on conductors -- there's too much of a desire to complicate matters by invoking coupled modes, conjugate matches, and the like, while it's really a simple problem that can be adequately and completely analyzed with nothing more than Ohm's and Kirchoff's laws. If it's not clear by this time, I doubt that anything else I can write will help.

You could download a modeling program such as the eznec demo and convert the existing NBS yagi to 170 mhz. I doubt there will be many plans for a yagi that frequency. Myself, I once built a 4 el yagi for exactly 170 mhz to listen to a local NASA feed from JSC. I ran the 3 el NBS converted to 170 mhz.
The reflector would be 33.89 inches.
The driven element would be 32.34 inches.
The director would be 32.01 inches.
From the reflector to driven element, the spacing would be 13.9 inches.
From the reflector to the director, the spacing would be 27.8 inches.
Feed with whatever matching device you desire. I usually use gamma matches as they are simple, and I haven't had any problems with them. 1/4 inch rod would be a good match to those dimensions. You could make the whole thing welded as one piece out of copper tubing if you have a torch. I built a 50 mhz 3 el yagi that way.

MK

If you do a web search for something like "2 meter yagi design" you should get lots of hits. Just scale all the dimensions by the ratio of design-frequency/your-frequency. For ratios near unity, you shouldn't have to worry about the element diameters, just scale the lengths and spacings.

Here's one of the hits I got:
http://home.att.net/~dale.keller/ham/antenna/yagi3.htm

Cheers,
Tom

My server is really messed up. I don't get half the usenet messages
for many days, while some appear right away.

Maybe it is a system wide problem.

>radiation.

Which is my point all along. What you do to the differential system is
totally different than the effects on the common mode system.

That is why your Ohms Law and power formulas used to calculate common
mode voltage exciting the balun won't work.

That logic gets you in trouble. That is why you calculated the WRONG
answer using formulas than can't be applied to the system, even
through the formulas are correct by themselves.

I have no more time for this Roy and Ian, but I appreciate your input.
I've come to the following conclusion.

Some of us realize there is no need for a physical path to ground
through a conductor to excite a feedline with common mode, some of us
won't even get to that point and think a dipole or other antennas can
be *perfectly* balanced or *perfectly* unbalanced without extreme
measures when in fact virtually all antenna systems are someplace well
between the two extremes.

My point was only that the common mode impedance and voltage in a
system is not related (or directly related if you prefer) to the
differential mode impedance and voltage, to which some others take
great exception despite mountains of examples where it can be shown
changing one might move the other in the opposite direction, the same
direction, or might not change the other at all!

In my mind, when the effects are such we are better off to start from
the view the effects are not related, than to start making wrong
assumptions that changing one always changes the other is a
predictable manner. Since some people refuse to believe that despite
direct examples, because they can think of ONE or even a few cases
where something seems to happen the way they want.

I've concluded it a lot like convincing my wife the wipers on my truck
are NOT swinging in time to the music on the radio and are not
related, while she argues that if I remove the battery or turn off the
key they both quit and that proves they are.

.....and if we vary the feedline length you can move the problem
around also.

The only balanced antenna on all bands is a perfectly balanced dipole
with a balanced feedline leaving for a long distance at exact right
angles at the antenna center, fed by a balanced source.

The other extreme is a perfectly unbalanced antenna, like a monopole
over an infinite groundplane with an unbalanced feedline extending
below the groundplane.

What often helps me is to think of the two extremes, and try to stay
as close to the desired one as possible.

Think about all the people who go around telling others that a
groundplane only needs two radials, when a groundplane even with four
radials can have significant common mode current on the feedline if we
aren't careful. We have to be careful because these systems are really
more complex than they appear.

Having actually measured loops, I disagree with that totally.

You will play hell finding a low ESR air variable capacitor, and have
an even worse time homebrewing one unless you know what you are doing.

The capacitor must have a very short length of current path, and have
the multiple plates in parallel so the resistance and inductance of
the plates are minimized. Also, most wipers in most capacitors are
pathetic in series connection resistance. While they are OK at a few
amperes normally found in high power amplifiers with modest Q tank
circuits, they are not adequate in circuits carrying dozens or
hundereds of amperes.

>There are two rotating disks, one mounted near each end of the rotor shaft.

>axis balance each other out.

Multiple sliding contacts with considerable pressure are certainly OK,
but a single disc for each plate is generally not a good idea unless
you hardly need any capacitance. Single band loops are very forgiving
for capacitor design if you make they large enough, but multiband
loops require a large specially designed component if reasonable
low-end efficiency is to be expected.

Partially.

I have melted connections and turned bearings blue in nomal air
variables at fairly low power (100 watts in a three foot diameter loop
on 14 MHz). While this might not indicate a large percentage of power
is initially lost in that area, it does cause the system to stop
working.

Swaping in different capacitors, field strength increases while feed
impedance and bandwidth decrease when the capacitor is more "square"
or compact in physical area without long rotor and stator shafts.

I've seen a general trend that the longer and thinner the capacitor of
a given construction, the worse they behave. I assume that is because
we are adding series inductance as well as resistance. It is a double
hit!!

I liken it to the difference between a multilayer chip capacitor with
a Q of 50,000 or more, and a ceramic door knob with a Q of several
hundred. Same materials, different physical layouts.

A capacitor tester I constructed actually was just a small loop in a
shielded box made from PC board material. Loops are great for testing
capacitors!

All the copper loop components can be silver plated before they're
fabricated into an antenna then the joints can be silver soldered
(sometimes called silver brazed). Since RF only flows on the surfaces
of conductors the net effect would be the same as using solid silver
components - at a huge cost savings.
>
>
The other advantage of silver being that as time goes on and antenna
surface oxidation creeps into the picture silver oxide is a good
conductor whereas copper oxides are not. This advantage of silver is
far more useful in reducing losses over the life of an antenna and
it's tuning cap parts than is the small increment of additional
conductance of silver vs. copper.
>
>
There is nothing new about any of it. There were a lot of
silver-plated components in the WW2 surplus radios I used to kick off
my ham career. Many of the old-time hams silver-plated the tank coils
of their big homebrewed amps. Particularly at vhf/uhf freqs where the
"layer of RF" is very thin on the conductors.

The resistance difference between silver solder and lead-tin solder is
negligable, there is very little silver in most silver solder.

Even if it was all silver, the connection current path LENGTH is so
short it does not matter at all.

The thing to keep in mind Mike is everything should be looked at as a
percentage of the overall system resistance in the loop element. As in
mobile antennas, you sometimes chase problems around. Most important,
there are limits as to how much you need to worry about each
component.

For example, you see large copper tubing coils on some mobiles on 75
meters. But the ground resistance, in series with that system, is in
the order of several ohms or higher. A number ten wire would not have
a discernable difference in a mobile antenna, because the SYSTEM loss
resistanbce is so high it swamps out the ESR change in the coil.

In your small loop, the two primary concerns are conductor current
area in the LONG loop itself, and the capacitor. With even a
reasonable sized conductor like 1/2 inch aluminum, the capacitor
becomes the main problem in a small loop. Improve the capacitor, and
then the conductor can be the problem...but it is mostly a surface
area issue rather than a material issue (unless you use something
silly like steel tubing).

Use a smooth large-diameter round conductor that you can work with (I
use aluminum because I can weld it, you might want copper because you
can solder it), and pick a good capacitor. You might look for a
surplus vacuum variable capacitor, if you can build a very good clamp
for connections.

Keep the loop as large as possible, and problems with resistance will
be less important!

Actually if you want to work only one band, a short loaded diople is much easier to make more efficient than a similar size loop.

With the source placed at the load, the currents in and out of the source
and in and out of the load seem to be in series. Add a transmission
line, and the currents in and out are no longer in series?

> You realize, of course, that your diagram doesn't include all the loads.

It includes the conceptual differential load for the conceptual differential
currents. I added the I3 current path above. How can I1 equal I2 in magnitude
with opposite phase and also satisfy the equation I1 = I2 + I3?

Uhhhhhh, Tom, assuming the effects are not related *IS* a wrong
assumption.

There you go railing again. I have never said that changing one
always changes the other. I have better sense than to use the word
"always" in a sentence like that. What you have tried to tell us
is that changing one never changes the other which would be a true
statement if they were truly unrelated. But you and I both know
that changing one often changes the other which proves that they are
related in some manner. That you are sometimes ignorant of the
exact relationship doesn't mean that they are unrelated. It just
means that you are ignorant.

What you are saying is that you would rather start off in error
and correct your error along the way. That's one approach but
please don't try to convince us that your error is really not
an error. If you were correct, common mode conditions would be
unrelated to differential mode conditions and it wouldn't be
possible to make any improvements since they are unrelated. If
they were really unrelated, you couldn't possibly be a common
mode expert, now could you?

Quite right - the resistivity of solder is about 10 times that of copper, but the amount of solder surface is only about one percent of the total circumference (unless someone is making very messy joints).

Alternatively, why not look for some scrap offcuts of large semi-rigid coax? The outer is corrugated solid copper, very easy to bend into the size of loop you want, and then almost self-supporting. It's also vinyl jacketed to keep the copper clean and bright.

With so much cellular base station installation going on, there are lots of scrap ends going straight into the dumpster, so you should be able to get it for nothing. This is usually the "seven-eighths" size, which is actually about 1.2in overall diameter.

Ignore the inside, and treat it as cheap, flexible copper tubing.

There is another error that is being repeated. The coax circuit is being modeled as a coax in conjunction with a "wire" that is somehow external to the coax and operating independently of the coax. The common mode current is assumed to flow in that wire and to be unassociated with the inside of the coax.

This external, independent wire idea is prevalent and is not correct, and leads to misunderstandings. A common mode current that flows on the outer surface produces a common mode voltage along the outer surface. This voltage is *transformer-coupled* to the center wire and constitutes an almost identical common mode voltage along the center wire. This transformer action is greatly enhanced by the presence of a current balun. In fact, that is one of the main features of the current balun: it inhibits the conversion of a common mode voltage *along* the length of the coax into a differential mode voltage *across* the coax. Without this transformer coupling, that is exactly what would happen.

The outside of the coax and the inside of the coax are not, and cannot be regarded as, separate and isolated entities. Coax is not that simple.

Gary,
I don't think it would be too critical at all,
and almost anything would work. I'm not familiar
with what the base of your antenna looks like, but
if there's a bolt on the 'ground' portion of the
antenna, that should work for a connecting point.

Hi Cecil,

To satisfy Kirchhoff, "where" is the current I3 flowing to? AND how
does it get back? Otherwise your question:

```
> How can I1 equal I2 in magnitude
>with opposite phase and also satisfy the equation I1 = I2 + I3?
```

is simply reduced to I3 = 0 (already illustrated); but then why add a
nonconducting wire to the problem?

Tom, W8JI wrote:
"---your Ohm`s Law and power formulas used to calculate common mode voltage exciting the balun won`t work."

The power formulas are Ohm`s law. Ohm says:
I = E/R
Power in a resistance is ExI.
To make Ohm`s law give power it is necessary to multiply both sides of the Ohm`s equation by E. Everybody knows we can do this without changing the equation.
Immediately you have ExI = ExE/R. Restated, Power = E squared over R.

When excitation of one circuit is produced by energy in another circuit, the coupling (relation) between the circuits is determined by measuring the current in the exciting circuit and the voltage produced across a second circuit which is caused by the current in the exciting circuit. The ratio of voltage to current measured as described is called mutual impedance and is a natural Ohm`s law expression.

Note that when a large current in the exciting circuit is needed to make a small voltage across the remote excited circuit, the ratio of E/I is very small. This means the coupling is small.

I`ve lost count of the number of times I`ve tried to explain mutual impedance, a measure of coupling and the relation between circuits.

If mutual impedance seems difficult to grasp, look for it in any good electrical text. Many include it and likely explain it better than I.

Best regards, Richard Harrison, KB5WZI

I intalled a standard 102" stainless steel whip and then began working from the inside of the ball mount with a 10 turn coil to ground, the coil came from the tank circuit of an old Swan 500 (parts chassis).

About 2 1/2 to 3 turns netted me an swr dip but only brought it down to 3:1, that was at the high end of the band.
I added a 6" solid piece to the base of the antenna and then checked swr, now dropped to about 1.6:1 but at the high end of the band.
Adding the spring to the system dropped it even lower now about 1.6:1 at 50.3 where I want it to be. The SWR goes up in both directions from 50.3.

With the current installation I have seen significant gain on tx and rx, a huge difference in recieved signal if the swr is above 2:1.

The next move will be to add a trimmer cap to flatten it out completly I hope, so far I am very pleased with the performance over the original 1/4 wave, although it was MUCH smaller. Thanks for all the input, there is alot more experimenting to be done.

Having spent several months now on 6, running simplex only to the house (usually) I have found that the weather and not just rain or sunshine have a significant effect on signal strenth from the fringe areas, cool clear days can improve the signal by what seems like 15db or more. Humid days=more signal loss, rainy days=huge signal loss. Has anyone else experienced this? Im talking about line of site or groundwave only.

Base antenna is a 5/8 wave wire vertical with 3 radials, mobile is the 1/2 wave, both stations running about 20w. Good communications up to about 20miles which may not seem like much but the local terrain is very hilly within a 10 mile radius of the base station.

Tim

Tom, W8JI wrote:
"I`ve concluded it a lot like convincing my wife the wipers on my truck are NOT swinging time to the music on the radio and are not related, while she argues that if I remove the battery or turn off the key they both quit and that proves they are."

That is a different argument. Tom`s wipers don`t supply power to his radio, and it is unlikely that his radio supplies power to the wipers. They can be switched on or off independently.

We can`t switch off our differential r-f power and not switch off our common-mode power. Common-mode in our examples relies upon differential-mode as its source.

It is absurd to claim a proven cause to effect is unrelated, yet that claim endures in this thread.

If you have the ARRL Antenna Book, 19th Edition, open it on pages 5-10 and 5-11 and take a look at Eqns. 13 and 14. If you have an older edition look for "army loop" in the index, you may find it this way. If you don't have any edition of the book, buy it, it's well worth its price :-)

There you see that a radiation resistance R_r of 100 mOhm (0.1 Ohm) is quite realistic on the 20 m band. And with a loss resistance R_l of 1 mOhm (note: 1 mOhm and not 100 mOhm like you wrote) we do get about 1% loss ["about", because it's not linear, loss [%] = 100*R_r/(R_r + R_l)].

So what we have been told about coax, that the physics of the coax forces the current on the center conductor to be equal to and 180 degrees out of phase with the current on the inside of the braid, is not true?

For buried radials, the radials protruding from the ground, support the
circle of wire. For elevated radials on a 4x4 wooden support, I just staple
the ring of wire directly to the wood.

Then the common mode current that we think we are measuring on the outside
of the coax braid using a toroidal pickup coil is really measuring double
the actual current existing on the outside of the coax braid?

Also, are there any common mode currents returning through the earth
rather than through the coax?

If I1 and I2 are the currents on the inside of a coaxial cable, I3 will
be zero. But if you add another load from I1 (representing the other
half of the dipole), I3 can become non-zero.

Why is this so difficult?

> 73 Tom

Yes. Even if you're careful to exactly balance the currents on the radials, considerable current can be induced on the feedline from coupling to the vertical radiator. It can take two baluns -- one at the feedpoint and another about a quarter wave down the wire -- to reduce this to a low value. The amount of coupling depends on the length and orientation of the feedline. It's an interesting problem to model with EZNEC or a similar program.

Hi Cecil,

AC/DC/RF does not answer the "where" it flows, nor the "how" it
returns. As drawn and described to say:
>Consider I3 the RF current flowing in 1/4WL of wire.
also begs the question, if there is a current flowing, where did it
"come" from? The Differential load already completes the only
source's current path, there is no external potential to cause a
branch to occur.

I can measure a radiated EM field associated with that extra wire. I can hang a toroidal pickup around that piece of wire and measure a current. I may even be able to get an RF burn from that wire. That's why it is so difficult. Saying that there is zero I3 current in that wire doesn't agree with reality. So is there something wrong with the model or did God fail to properly design reality? (A rhetorical question :-)

In other words, would you grab one terminal of a dummy load being driven by 1000 watts because the RF current supplied to your body by some math model is predicted to be zero? I sure wouldn't!

Just "No"? Can the inside wire of coax carry common mode currents or not?
It has been reported here that when the inside wire of coax is tied to the
braid at both ends, the inside wire will not carry any RF. I'm confused.

>constitutes an almost identical common mode voltage along the center wire.

Surely this common-mode voltage is transformer-coupled to both the
center conductor and the inside of the shield - equally and in phase?
Then the differential voltages and currents inside the shield are not
affected.

Therefore the points I was making about symmetry (or lack of it) at the
feedpoint are not affected either.

> This transformer action is greatly enhanced by the presence of a
>current balun. In fact, that is one of the main features of the current
>balun: it inhibits the conversion of a common mode voltage *along* the
>length of the coax into a differential mode voltage *across* the coax.
>Without this transformer coupling, that is exactly what would happen.
>
There's a different way to look at that. The alternative name for a
so-called current balun is a feedline choke, and that better describes
its intended function of creating a high impedance against the flow of
current on the outer surface of the shield. If this current is reduced,
the currents flowing in the two arms of the dipole are forced to be more
equal, and the whole system is forced closer to symmetry (though it can
never completely get there).

Obviously the presence of inductance creates a longitudinal voltage drop
along the outside of the shield. Magnetic coupling transfers this
voltage to the inner of the shield and the center conductor as well, but
these two induced voltages are in phase so they appear as common-mode;
they do not affect the normal differential-mode behavior of the coax as
a transmission line [1].

While acknowledging that these effects inside the coax are real and
true, they are not relevant to this particular discussion.

>The outside of the coax and the inside of the coax are not, and cannot
>be regarded as, separate and isolated entities. Coax is not that simple.
>
Indeed not, but it can be simplified for certain purposes - including
the purposes of this particular discussion.

[1] There is something that <does> affect the differential-mode
behavior of the coax as a transmission line. When the feedline choke is
introduced, the currents at the feedpoint will change. Previously the
outer of the coax was acting as an unwanted part of the antenna, but in
fixing that you have actually changed the antenna system. Naturally this
will result in a change of load impedance at the feedpoint, and as seen
by the transmitter at the other end of the transmission line.

Sorry, you can't subpoena that information using Kirchhoff's law.

Kirchhoff's law states only that the (algebraic) sum of all conducted currents flowing into and out of any point within a circuit is zero. It requires no information about the external circuit conditions that create and drive those currents.

If you can use a sectional screw together antenna, the Shakespeare military AT-1011 series is a great choice. It is made of 4' fiberglass sections and are used as a 16' or 32' whip. The 16' size is what you see folded over the front end of HUMVEE's and there are many fixed, folding and spring bases available. The 8 section 32' whip and a canvas carrying case goes for about $125 surplus and bases run $25 to $125 - check surplus dealers like Murphy's Surplus in San Diego or www.american-milspec.com. I use the 32' version fed with an SGC auto tuner and there is a HUGE advantage on the lower HF bands compared to Hamsticks and other short loaded whips.

CAM, W5DXP wrote:
Just "No?"

Common-mode signal is caused by a differential-mode LOAD imbalance. It isn`t caused by the balance of energy inside the coax. One side of the common-mode source is the structure named the "antenna" which is out of balance. It has a surplus or deficiency of charges and current in regularly repeated instances due to the inherent imbalance.

The other side of the common-mode source is the coax exterior. It shares excesses with the structure named "antenna".

Energy is exchanged between these sides of the common-mode circuit by displacement current. Earth may or may not be involved depending on its proximity.

Hi all-

I was thinking of purchasing Cushcraft's A2706S or A27010S beams, and I'm leaning towards the 6s for it's smaller footprint. I was hoping some helpful hams out there might lend an opinion or two about these antennas from experience. Primarily, the antenna would be for local ragchewing to hams within a 10 mile radius. Any experiences with these antennas out there?

Hi Cecil,

Bill offered a perfectly suitable explanation. It relates to
exceedingly simple transformer mechanics: if wires migrate through a
core, one current that appears on one must appear in (couple to) all
(insofar as the ability of the source to support the load - and the
style of magnetics almost guarantees it).

Again, this is the sense of Common Mode that is described in all such
definitions of this configuration. It is also part and parcel to this
gassing on about "relationships" and coupling, and mutuality and ....

A complete diagram of the circuit would resolve much of your
confusion.

Hi Ian,

You don't know either....
(Hint: satisfy what little you admit of Kirchhoff - if you can,
explain that for the current that leaves, denoted as I3, where is the
current equal to I3 and returning to that same point)

Solution, there is no loop (first violation). There is no potential
applied (second violation). There is no load (third violation). It
takes only one violation, not all, to dismiss this wire as being a
rhetorical ornament.

Why indeed ? It is an elementary matter of network analysis.

And although you well understand what goes on, it seems you are unable to convey the basics because you insist on over-complicating the issues you have all waffled yourselves into.

Try drawing the most simple network on a piece of paper. Get rid of the in-essentials. Make sure it is COMPLETE. Contain it to the near field. Then there will be no loose ends where current leaks out into outer space.

I am trying hard not to overcomplicate matters myself.

Begin with color of Cecil's motorbike.

Yours, Reg.

Richard Clark wrote:
"The Differential load already completes the only source`s current path.
There is no external potential to cause a branch to occur."

Richard Clark must be considering the coax connected to a resistor. In the case of coax connected to an unbalanced antenna, there is an unbalanced external potential between the antenna and outer shield.

Don`t take the "Cecil Challenge", Richard. I`ve seen what happens to birds on a transmission line.

Best regards, Richard Harrison, KB5WZI

1164. Degen Designs (Home of the BBQ) Announcement

July 14, 2002 We regretfully announce that an important part of our team and my dad (VE3 CVS, Erwin Schweigl) passed away on July 11, 2002. He will be missed by myself, my family and all those that he touched. We will continue in his footsteps to provide the products that he helped develop. (Posted on our site).

Many have seen our selected postings over the years suggesting our antenna solutions and have been nice enough to visit our site to see what we have to offer (and not send us any flame mail or postings).

Thank you.

We hope to continue in this fashion to earn your support and respect as a manufacturer and developer of antenna solutions.

Again thank you,

Guenther Schweigl

He's one of my heroes as well. Fot those interested, an excellent (IMHO) biography is provided in Paul Nahin's book "Oliver Heaviside: Sage in Solitude, The Life, Work, and Times of an Electrical Genius of the Victorian Age". The publisher is IEEE Press; the ISBN is 0-87942-238-6.

Another interesting book that discusses Heaviside's contributions is "The Maxwellians", by Bruce J. Hunt. The publisher is the Cornell University Press; the ISBN is 0-8014-2641-3.

With regards to the mathematicians of his day criticizing Heaviside's operational calculus, one of my math professors (discussing Dirac Delta functions while teaching a group of Physics majors) told us to follow our physical instincts - if we get the right answers and the method seems to be right, mathematicians will spend the time to develop and prove the necessary theorems. Of course, he discussed Heaviside's contributions in detail, giving me my introduction to the man's accomplishments.

Tim

We have a point X defined by Cecil to have one current flowing in and
two currents flowing out. I1 and I2 are of the same magnitude. I3
can only be zero current (there is nothing left) and yet Cecil
maintains:
>Consider I3 the RF current flowing in 1/4WL of wire.
and who's on third?

Are we selling dummy loads with whips now? ;-)

Well I think people got to start building then iron out the details of resistance excetra. Frankly a soldered joint has very low loss that's not worth worrying about.

Get building and discover what matters and what doesn't. My loop is soldered and performs very well.

From: Brooke Clarke <brooke@pacific.net>
Message-ID: <3D3246EC.79EE1B99@pacific.net>
Source record: 138609

Hello:

The AB-1135 is being sold you know where.
It will hold the 3 meter long combination AT-271 fishing pole whip & it's spring
AB-591 base.

Would a magic length of 75 Ohm coax match it to 50 Ohms 51 MHz?

If not is there a very simple coax in line way to match it at 51 MHz?

73,

Brooke Clarke, N6GCE

Source record: 138610

A small piece of copper plate or sheeting can be drilled around the outside for as many attachments as desired. Then solder the radials into place.

The sheet copper of various thickness can be found at a local sheet metal shop, or ordered from several places on the internet.

1171. Re: How To Measure Antenna Impedance?

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-15 05:21:22 UTC
From: k7itm@aol.com
Message-ID: <3200347.0207142121.539ca41f@posting.google.com>
Source record: 138612

Unfortunately, it's not trivial to measure impedance to 10% accuracy
at 900MHz. Best, perhaps, would be if you can get your hands on a
modern network analyzer with an S-parameter test set, preferably one
you can calibrate to read at the end of a short feedline. If that's
out of reach, here are a couple suggestions that will get you in the
ballpark:

1. Build your own return-loss bridge and detectors that can measure
the in-phase and quadrature components of the reflection. Expect to
use some very good construction techniques. That's essentially a
network analyzer.

2. Measure the SWR. Put an L-network (or other simple matching
network) between the bridge and the impedance you want to measure, and
adjust for a match. Find the impedance you matched to from the values
of the L-netowrk components. This presumes you can keep parasitics
very low and you can measure or calculate the values of the components
accurately.

Um...good luck, too.

(Do you really need to know the impedance, or can you simply match it
to your transmission line?)

Cheers,
Tom

Lance Johnson Engineering makes (made?) a cast ground plate. It's
solidly built and should last a lifetime, but it's priced accordingly.
The poor ham's copy is a round aluminum pan (pie pan, pizza pan,
etc.), with sheet metal screws placed around the rim and a hole cut in
the middle to pass the vertical through. Run a short piece of salvaged
coax braid from the pan to the antenna ground screw.

It works. But you could just as easily use a loop of bare wire, as Cam
said. Bonus: the wire loop won't leave a dead spot in the grass when
you move and take down the antenna ;^)

1173. SM0VPO Homepages Update

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-15 08:39:48 UTC
From: Harry SM0VPO <someone@microsoft.com>
Message-ID: <agu2o0$h2a$1@newstoo.ericsson.se>
Source record: 138614

Hi all,

It's been quite a few months since I last posted anything here, in fact it is about a year ago. Harry's Homebrew Homepages is now located at http://w1.859.telia.com/~u85920178/ where there are no banners to slow down the traffic. There are no outages due to excessive traffic since there is no bandwidth limit. It is just a bloody dificult URL to remember! But work on antennas and radio equipment is always in progress.

During the past year, I have been hounded by demands for payment to "freeservers.com" (or should that be "FEEservers"?) so I have moved the page http://sm0vpo.8m.com to http://w1.859.telia.com/~u85920178. Some of you may be aware that PMP3.NET was hacked and eventually closed down due to the misuse. This took away my free homepages that were kindly hosted by PMP3.NET.

There is a new messageboard too, also without banners. A new FAQ (Frequently Asked Questions) and FASQ (Frequently Asked Silly Questions). All the old ones have been kept, but some new ones have been added, Eg: "How many volts do I need to kill someone?". During the past 12 months, Harry's Homebrew homepages (http://w1.859.telia.com/~u85920178/) has had quite a few additions. Some of the latest project examples include:

EPROM AF Generator (still under construction).
WAV to EPROM conversion.
Many synthesiser projects.
DC-DC voltage converters.
150mW FM TX (88MHz - 108MHz) (technique Ok for 145MHz).
Synthesised FM TX (88MHz - 108MHz) (technique Ok for 145MHz).
Antenna Z bridge for Spectrum Analyser.
Antenna Questions & Answers (Eg: "Size isn't everything!").

H.H.H. now has just three sites, but no mirror sites. they are all located at:

PROJECTS - http://w1.859.telia.com/~u85920178
Unlimited bandwidth, Full site, No advertising, SWE

VISITORS CIRCUITS - http://hem.spray.se/lythall
Selected visitors submitted circuits - SWE

PDF LIBRARY - http://hem.passagen.se/sm0vpo
Unlimited bandwidth, Full site, SWE

So perhaps I may have the pleasure of a visit from you. Whatever you do, have fun with antennas, homebrew, radio and electronics in general. Very best regards from Harry Lythall - SM0VPO

I repeat my challenge, Richard. Are you willing to drag your private
parts along that wire when the source is 1000 watts in order to prove
there is no RF current in that wire? If I1 equals I2, your private
parts should draw zero current, right? How sure are you of your
convictions?

> 73's
> Richard Clark, KB7QHC

ah, but here you are mixing your laws. kirchoff's applies to a point, you can add all the currents at a point and they must equal zero. BUT, you can NOT say where those currents go once they leave that point. the current I3 can flow down a 1/4 wave wire, reach the end, reflect back and show up some later time at that same point, at which time it must again sum up with I1 and I2 to be zero, but at that time the current component of I3 that has reflected from the end of the wire can be added back into I1 and I2 (which may change because of this new current component) to make the law work again. now if there were a resistive load at the end of that wire that happened to match the impedance of what ever propagation mode I3 sees as it travels along it's wire then the current goes into the load, heats it up and never gets back to the junction point, but I1, I2, and I3 still add up to

zero.

to properly analyze what happens to I3 after it satisfies kirchoff's law at the junction point you have to analyze all the various possibilities including ohm's contribution that removes energy as heat, and all the possible fields and waves generated by the moving electrons according to maxwell's equations.

if the 3 points with I1, I2, and I3 are all connected at X then the currents
I1 and I2 will ONLY be equal in the steady state solution where the source
is DC. In ANY other case, including the transient response to turning on a
DC source there will be some current I3 and I1 will not equal I2.

haven't you ever used a dummy load with a whip?? didn't the ARRL expose a
company selling a dummy load as an automatic instant antenna tuner several
years ago?

From: David Robbins <k1ttt@arrl.net>
Message-ID: <agug5k01ahr@enews2.newsguy.com>
Source record: 138521

no, there is not magic combination. a 3m long antenna on 51MHz will be about 1/2 wave long. this will present a very high impedance(call it Zf) at the feedpoint. you can transform that impedance along a piece of coax to get any impedance from Zf (at even 1/4 wave lengths from the feedpoint) down to 1/ZF (at odd 1/4 wave lengths)... somewhere along that you may find a 50 ohm real part of the impedance, but there will be a large reactive component at that point. if you can find that point you can then add another coax stub to cancel the reactive component. design of stub matches like this are discussed in various texts... but the most basic problem you will have with this arrangement is that you are starting with a near 1/2 wave antenna which will be hard to match with any method, cutting it down to about 1/4 wave or extending it to about 5/8 wave would make it easier to match.

> "Roy Lewallen" <w7el@eznec.com> wrote:
> Why is this so difficult?

Perhaps because the network to be analyzed should really be:

+-------------------------------------------------I1->-+
| |
Source1 Load 1
| |
+-------------(Ground Plane)-----------------------<-I3-+
| |
Source2 Load 2
| |
+-------------------------------------------------<-I2-+

If Source1 = Source2 AND Load 1 = Load 2, then I1 = I2, I3 = 0
and I1, I2 can be considered purely differential.

For any other condition, there will be a non-zero common-mode
current I3 and I1 will not equal I2.

If you think this looks like a Wheatstone bridge composed
of two voltage sources and two loads, you might be right.

Hi David,

You reading all of this from the eh handbook?

It is not all that difficult - except when playing with less than all
the facts (an obvious shortfall of the circuit description).

Still, no one, not even the author of the model, seems to be able to
answer how more current leaves a point than enters it.

Tim Groat wrote:
"Lance Johnson Engineering makes (made) a cast ground plate."

A ground plate of aluminum or nagnesium connected to copper and buried at the earth`s surface won`t likely last long even if coated with petroleum jelly.

Metals close to each other in the galvanic series last best when connected where they can become moist.

Broadcasters surround towers with copper sheets. These are brazed together and 120 radials plus other connections are brazed to the sheets.

For ham installations, Cecil has a practical idea. Surround the tower with heavy copper wire. Attach your radials and other connections to this loop. Use copper to avoid erosion.

You don`t need to braze or solder for good connections. Nicopress would be fine, but expensive. Burndy (split-bolt) connectors can be tightened for permaent connections.

Best regards, Richard Harrison, KB5WZI]

Hi Jim,

While I don't necessarily agree with your conclusion, you at least are
giving the poor model a much needed brush-up. This posting has pushed
the thread to over 200 messages, and all too few are willing to look

at the circuit.

Imagine, it simply answers the question where does I3 go without all that anguish about life and the universe being unknowable. It also offers a source, a load, and a loop. It also points out how miserly the original description was to sufficient details ("context" as it was called). To this point, nearly every bobbing head posting here was agog with disbelief that this was achievable. It describes a simple Kirchhoffian solution that for these same 200+ postings refused to acknowledge was possible (much less necessary).

Brooke Clarke wrote:
"Is not there a very simple coax in line way to match it (an end-fed near 1/2-wave) at 51 MHz."

Not exactly. Brooke may not have the latest ARRL Antenna Book. Too bad. Page 16-25 of the 19th edition of that book shows a "Super-J" maritime antenna.

A 1/4-wave short-circuit stub at its base provides an adjustable match for coax to the high impedance of the end-fed antenna.

A parallel-tuned resonant circuit can work in place of the short-circuit stub. Just move the coax attachment tap on the coil up from ground for a match.

I don't need to know the how and why to be able to measure the
current in that wire. But forget the wire. Would you grab one
terminal of a dummy load that was in the process of dissipating
1000 watts of RF (since you can prove on paper that zero current
would flow into your body)?

If possible, the 6mt yagi at 6 mt over the roof and the 2 mt yagi 2 mt
higher.
Half heights could be still acceptable.

1193. Confusing Conundrum

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-15 17:38:19 UTC
From: SideBand <abNO8SPAMlr@csotbs.org>
Message-ID: <3D33088B.2000903@csotbs.org>
Source record: 138534

Here's the deal.. I'm planning on running HF mobile in the truck. The problem is twofold here:

1. The truck body is mostly fiberglass, which makes it difficult to find a ground.
2. When a ground is found, it is invariably plagued with noise from the fridge and the inverter.. (I know... don't run the fridge and the inverter, right? Well, then my milk goes bad and I can't charge my cellphone.)

So, I'm looking for a solution that will eliminate these problems. Isolating the RF ground from the body by setting up a separate counterpoise of some sort seems to be the way to go.. It worked on the 2M set, anyway.. The problem with that is size...

I'd also thought about dipoling two screwdriver antennas, or a pair of hamsticks for each band I'm interested in, but again, the size issue...

Any ideas?

You might look into the Cushcraft A627013S 6 Meter/2Meter/70CM
beam antenna. It's all three on one boom. It might save you a lot of
problems on the mounting.

who said anything about more current leaving a point than entering?
kirchoff's law is clear on that point. but you can not describe the loop or
where the current goes once it leaves a point using kirchoff's law and the
simple wire model being shown, you would have to add in displacement
currents and induced currents at every infinitesimally small wire segment
all along that wire to figure it out.

Hi Doc:

The idea is that the PRC-25 radio comes with this antenna and the AB-1135 is a ground mount that will accept the antenna and uses the same mounting hardware as is on the PRC-25. When the AT-271 is installed on the PRC-25 there is built in matching network but when the AB-1135 is used then some other matching needs to be done. Maybe a network in a box to be placed in line at the base of the antenna?

Does anyone know how the AB-1135 was intended to be used?

Hi Aaron:

You might look into military mast sections as carried by Fair Radio and many others.
Many years ago, and for a number of yerars until a storm took it down, I had a 50 mast for a longwave beacon.
It took two people to lift it up. Use 4, not 3, anchor point for the guys so that the left and right guys will help stablize the mast as you tilt it up. The layout and install instructions are in the manuals for many military antennas that use this system.

I now have an OE-252 antenna that been up a few years on one of these.

Some of the answer depends on the kind of antenna(s) you plan to use.
For rotary beams I wouldn't use either fiberglass or aluminum masts.
Both could well wear very quickly in the usual hard tower-top sleeve
steel tube bearing vs. a steel mast. Both are difficult to find except
in large industrialized areas.
>
>
Continuous 15-21 foot lengths of fiberglass pipe are out there for the
process industries but you can bet it's extremely expensive and so is
the shipping cost. Run a search on "fiberglass pipe", you'll get a lot
of hits. Your best bet for finding aluminum is your yellow pages under
"metals". Aluminum pipe is usually available locally as electrical
conduit but the aluminum alloy used for conduit is very soft and not
nearly as strong as are the much stronger aircraft alloys like 6061T6
which is the minumum I use for antenna work.
>
>
Fiberglass has the additional disadvantage of being non-conductive
which is not good when antennas should be grounded for both proper
performance and lightning protection purposes.
>
>
My suggestion is to stick with galvanized 1 1/2" steel pipe which is
the ham-standard mast material. It's comparatively cheap, it's
thoroughly proven, wear-resistant, conductive, strong and it's
available in 21 foot lengths everywhere and it can be dragged home
without having to spend any money on shipping the stuff.

>(freq < or = 900 Mhz).
>
>How do I do this>

Its more work, but scale the antenna down in frequency, and use one of the
vhf rf bridges,
The ITT rf handbook covers use of q-meter to measure impedance. taint easy.
Check the nearest university. They may have the gear you need.

My two cents:

Probably some big capacitors or filters will cure your refrig noise problem.
The iunverter is another issue. You'll never it it quieted down. Best
solution is kill it when you want to run the SSB.

From: k7itm@aol.com
Message-ID: <3200347.0207151152.41197bbc@posting.google.com>
Source record: 138547

I don't know the exact antenna system you posted about, but I assume
your 3-meter length description is accurate. Also, I don't know
exactly what you are feeding it against. Those factors will cause
some variability in the answer, but it's key to note that you have an
antenna just about half a wavelength long, which means it's a bit
above the halfwave resonance. A half-inch diameter 118" long antenna
fed against a perfect ground plane at 51MHz will have a feedpoint
impedance of _roughly_ 300-j400 ohms. If you're insistant on using 75
ohm line to match that, I'd suggest what's essentially a resonator:
about 70 electrical degrees of line in series from the antenna to
where you attach the 50 ohm feedline, and another shorted stub about
15 electrical degrees long attached at the point where the 50 ohm and
75 ohm series lines connect. The total 85 degrees length is resonated
by the capacitive reactance of the antenna. (I'm sure Reg will pick
right up on that one. ;-)

There are any number of other ways you can match that sort of
impedance to a 50 ohm feedline. A simple L network will do it: about
9.8pF across the feedpoint and about 620nH in series to the feedline.
That's also a lot easier to adjust than the coax stubs.

Cheers,
Tom

Cecil's drawing (not mine):
>> CAM wrote:
>> > Aren't I1 and I2 in series?
>> >
>> > +---I1->-+
>> > | |
>> > Source differential Load
>> > | |
>> > +---<-I2-+ X
> |
> ----------------------------<-I3-+
exhibits one current entering point X and two leaving. The current
entering (identified by Cecil, not me) is I1; the currentS leaving
(identified by Cecil, not me) ARE I2 and I3. Per the standard
understanding of differential current as offered by Roy above, I1 and
I2 are equal (as confirmed by Cecil, others, and not simply me).

It is not a question of metaphysics nor is it unreasonable to ask: where is that current going? And further to balance the currents - at point X alone - requires more of this drawing than is offered; and that has been in fact already attended to by Jim Bromley, K7JEB.

So the technical issues can be resolved through discussing Jim's model, or the obviously more interesting philosophical questions of genital relationships (identified by Cecil, not me) with the poorer model can be pursued with the drawing above.

Radio amateurs suffer from delusions of accuracy when making measurements.

Why don't most contributors to this thread go back to square one and Ohm's Law and exercise their reasoning powers. I'm sure some of you have some.

The nonsense exceeds that generated by discussions on Reflections and Conjugate Matches.

But why should *I* spoil your enjoyment ?

Gentlemen, here's to your good health. Can I top up your glasses ?

The easiest way to do this is to use one of the "Yagi calculators" on the
web. They are pretty basic but very simple. Just enter the frequency and
it will spit out the element lengths and spaces.
http://www.nemr.net/~aschmitz/antennas/calcantenna.html

Try the link above. I'm not sure if its the best one, but its just the
first one that popped up using Google.com.

this thread has gone on so long that we are all talking about different things now. if indeed as you say the points marked with the +'s above are all connected together and the differential load is indeed before that connection point the whole thing is rather stupid as you have a short circuit across the line after the load. i had been reading it as a distortion of a dipole connected (the differential load) at the points where I1 and I2 are marked then the extra wire carrying I3 was representing the outside of the shield or alternately some other wire hanging off one side unbalancing the load. the whole thing has been twisted around so much that any statement made at this point could be supported or refuted by any other statement based the the writers interpretation of the problem and their own viewpoint.

Oh boy! Not enough information to really help much, but here goes.

Fiberglass truck? Must be an over the roader, huh? Do not confuse ground with groundplane! If it is a semi, or other large tractor, about the only place you have any substantial metal is the front bumper. Not an ideal place to mount a mobile antenna, but better than none. One of my long-time friends just retired from long haul, and ran mobile for many years. His antenna was a home brew one with a 6 foot copper mast, heavy duty Texas Bug Catcher coil, and a manual tuner to take care of the other bands besides 20. Worked that guy ALL OVER!

As for the noise, there are about as many solutions as there are noises. The best solution is not caps as they require splicing into the lines, which isn't all that smart of an idea. Palomar Engineers, and other sell several different sizes of split ferrite beads which slip over the existing wiring. They get very lossy over about 1 Mhz, so they do a good job of noise reduction.

There are so many other variables, without further information, it is hard to pin down solutions. I personally have been mobile for over 30 years, have owned about 10 radios in that time, and some 20 vehicles. If experience pays, my dues are caught up for about another 10 years, I think.

Brian:
Water pipe is a poor choice for structural material. It is designed to be malleable, and have high hoop strength, but is not very strong for its weight in any other mode. A commonly available material which is designed to be a structural member is the various sizes of chain link fence post material. You have to go to a fence installer, as the do it to yourself stores only stock one or 2 sizes and in short lengths, but real fence places will have raw stock in many sizes and 21 foot lengths like water pipe. Much lighter if you have to haul it very far up a tower, and much stronger in bending moment. There are also some black structural pipes which meet the strength criteria, but also not found at your local stores.

Gary,
We used to use a buried "heavy" copper conductor in
a circle around the base of the mast and connected the
radials to this. It worked well in most cases. The
exceptions were short aerials and soil which had quite
different conductivities when wet than when dry. Used a
copper sheet to stabilise the base impedance in this case.

All joints were made using phos-copper welding rod
and oxy-acetylene equipment. This overcame corrosion
problems.

Matt,
A few of the tower manufacturor's used to offer
steel masts. No idea if they still do, but it's
worth a try. Depending on the antennas mounted on
the mast, the mast may be a real 'hog', weighing as
mush or more than a section of tower. It may seem
like 'over-kill' but it really isn't. Good luck.

Can anyone tell me witch dual band HT's and mobile radios can both receive and transmit at the same time??

I have only found the Kenwood TH 79a and HT that while you are transmitting on 2 meters you can receive on 440.

Again are there any other HT's and Mobile dual band Ham radios that can simultaneously receive and transmit at the same time?

I saw a set of steel masts from Rohn in the R & L Electronics catalog
that I downloaded a couple weeks ago. Up to 50 feet tall. Catalog is
big, so if U don't have hi speed access, count on a wait to download
it.

R & L website here:

The Kenwood TM-742A mobile (tri-bander) can receive on the other bands
while transmitting on one band.

Any "true" dual bander will do this. The Icom 207 or Yaesu FT-90 won't. They aren't true dual banders.

Hi all,
So far I have not seen a reference to the good old cheapest place to
get metal pipes, plates, angles or any combination of said pieces.
The JUNK YARD. Or more politically correct, the recycling center ;<}
I have found steel plate for tower base/parts, pipe of various
lengths, aluminum plate for rotors and just about any steel or
aluminum angle you can imagine. Not only can you find lots of good
stuff, the price is usually pennies on the dollar when compared to
new. Yes, I know, there is usually a little work involved in getting
it painted or polished up and you have to drill your own holes but,
isn't that part of the fun? I have found that when you frequent these
establishments it is possible to leave a note up, for the operator of
the scale, with request for the particular parts you are looking for.

Besides if I read his request correctly, this will be a receive only
antenna. The "fine tuning" is a lot less critical with no SWR
ajustments to deal with and a basic yagi can work wonders. (he says
after having built a rough yagi out of a stick and 4 coat hangers to
DRAMATICALLY improve my reception for 88-108mhz broadcast band FM at
my backcountry house where reception was zilch)

Do like we do in the Broadcast Industry... Use 3/4 inch soft copper tubing, fill with sand, bend in a circle that will fit around tower base, "Silver Solder All" connections. Use coupling on end to end of loop. Then "Silver Solder" 120 1/4 wave radials (3 Degrees apart), and inter space with another 120 shorter radilas... ALL silver Soldered. A "Lawn Edger" PULLED backwards will cut a 4 1/2 inch by 1/4 inch slot to push the radial into. Use a 4 foot tubing with a guy wire "Thimble" hose clamped to the end iof the tubing to push the wire into the slot :-) I use THHC number 14 solid wire in 500 foot rolls. About 11.95 at Lowes.

Well Bob, that was very helpful.

If answering questions pisses you off that much,
why did you waste your oh so precious time composing
the one-liner?

Geezus fellah, get a grip!

The preceding is a perfect example of why Amateur
radio is going downhill. Fellow asks a perfectly reasonable
question and some old fart, who apparently has no
clue, give a mean spirited, vile one-line reply.

Thanks a lot Bob, its guys like you who are slowly killing
what was once a very nice hobby.

Of course, 'ol Bob is probably the nicest fellow in person.
Stands to reason that he would not answer like that if the
person asking the question could reach out and smack him
upside the head as he so richly deserved!

Well, my comments are not answering the original question
either so its back in the wood work for me.

Well, I guess my one-liner wasn't as funny as I thought it was. Sorry about that. But it was based on whether or not you can really "clean up" the rfi on one of these little, inexpensive inverters that go into cars & trucks. The solution might be more expensive than the cost of the inverter itself.

I notice that Radio Shack has some true sine wave inverters intended for high quality audio use, but they're priced at $859 and $1349 respectively.

Otherwise, no offense intended -- have a good day.

The feature is called "cross-band repeat." It should be clearly stated on the radio's description. These radios can simultaneosly receive two VHF signals, or two UHF signals, or one VHF and one UHF signal. And they can transmit on one band (VHF or UHF) while receiving on the other. Or they can act as a cross-band repeater. My Alinco DJ-G5TH does all this as do many (but not all) dual band radios.

It sounds great, but in reality it's not all it's cracked up to be. Do you really want to be monitoring one frequency when you're transmitting on another while you're motoring down the highway?

Agreed, the common mode current is *defined* by that particular mathematical expression, and... your comments are definitely true but when they are tendered in that way your comments tend to make common mode current seem more like a mathematical illusion... which it is not. The common mode current definitely exerts forces and can cause actions.

BTW... which current does a *clamp on* ammeter read when clamped around two conductors?

Is that clamp on ammeter instrument reading a *real* current, when clamped around two conductors? How about if it is clamped around Litz wire?

Is a current flowing when an individual electron passes by?

For how long does it flow?

What if two electrons pass by each other closely, but in opposite directions, and at different times? etc...

Agree 110% Nothing more irritating than talking on one band and
the other band take off 'talking' it's a real PAIN. I always kept the
radio function set to mute the subband when the primary band
was in TX. Makes any radio a LOT more friendly :^)

I've looked at their site a couple of times, and it seem to me the poles are 35 feet long, which is longer than each leg of a 40 meter dipole (ï¿½ 32.5). A wire down the middle would suffice, however, you can buy telescoped aluminum tubing from several companies. They tend to be light than glass, and and there are all sorts of mounting hardware available too.

David Robbins wrote:
"This thread has gone on so long that we are all talking about different things now."

Flat-world types had no logical support, refused to admit error, and introduced many diversions to turn attention away from their nonsense.

The source of energy is the r-f transmitter. One of its terminals is positive when its other terminal is negative. Via a coax transmission line this is a differential-mode signal source to what we would have as a balanced load, a dipole.

Most of this thread considered coax as the transmission line. The shield is likely grounded at the transmitter. The signal is launched between the inner surface of the shield and the outer surface of the center conductor of the coax. There is no r-f communication to the outside world at the transmitter. It is prohibited by "skin effect".

We have differential-mode propagation inside the coax even though it is considered an unbalanced line. This isn`t as strange as it may seem. The insides of the coax are a common-mode choke.

A common-mode choke may be considered as a 1:1 transformer between two coils. Current in the same direction (common-mode) in both coils cooperate in producing "counter-emf". This inhibits the current.

Differential-mode current through the coils is flowing in opposite directions, cancelling counter-emf production, and allowing current to pass.

Look at the equivalent circuit of your coax and its common-mode choke possibilities are apparent.

We agree the exterior of the coax is subject to common-mode current. We agree that the only source is the differential-mode energy from tnside the coax. All responsible definitions say dependent is related. That doesn`t deter the flat-earth people.

The point that imbalance enables common-mode to appear on the coax hasn`t been refuted. Ergo, no imbalance, no common-mode.

Common-mode current must have a generator with two terminals. One is obvious. It is where the inside of the coax shield meets the outside of the same shield. That is, at the load. Since energy can`t escape at the transmitter end of the coax, the other terminal must be the unbalanced antenna. How is this circuit completed? The same way the circuit between the two halves of a balanced dipole is completed, displacement current.

Pseudo-science has been invoked to present a wide array of nonsense, and I claim to be a non-participant in this promulgation of baloney. The answers are simple.

Best regards, Richard Harrison, KB5WZI

The difference current.

"Is a current flowing when an individual electron passes by?"

A charge moves, a current flows.

"For how long does it flow?"

As long as there is a path and until the charge is equalized between sites.

Reg, G4FGQ wrote:
"Is american "silver-soldering" the same as UK "brazing"?"

I expect not. Brazing rods are used for the soldering called "brazing" in the US. Silver-solder may be a rod also, but it usually requires only a propane torgh to melt versus an acetylene torch usually required for brazing.

I Bought one of the World radio poles.

It is a South Bend Sunny Day 21 foot fishing pole (SD21). The last section
is solid. My friend calls it a "perch pole". If you search the net for
South bend pole you should find more details on it.

You can hold it out horizontal, no problem. It won't bear any weight to
speak of vertically as it telescopes down if you do.

It is made from a single piece of tapered fiberglass tube. It is cut into
sections, then telescoped together from the "large end" so that as you pull
it open, eventually the sections "jam" into each other.

I use mine to thread wire antennas through trees.
I broke the tip of the last section off, so I taped a new loop on the end.

Well worth the $20 I spent on it.
KA9CAR

OTOH, the remote cross-band repeater function is pretty handy when
hiking with a large group over hills and through dales.

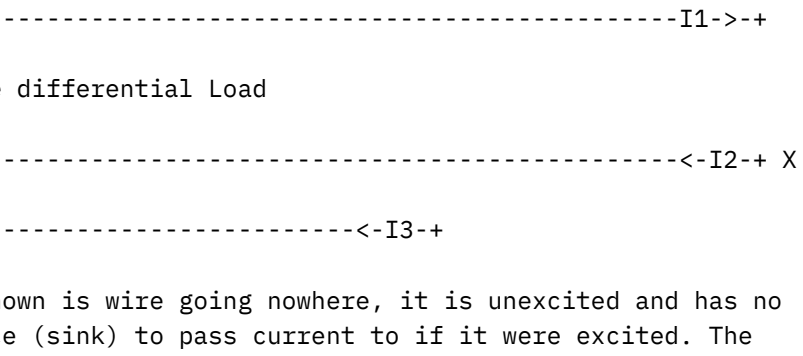
Hi Jim,

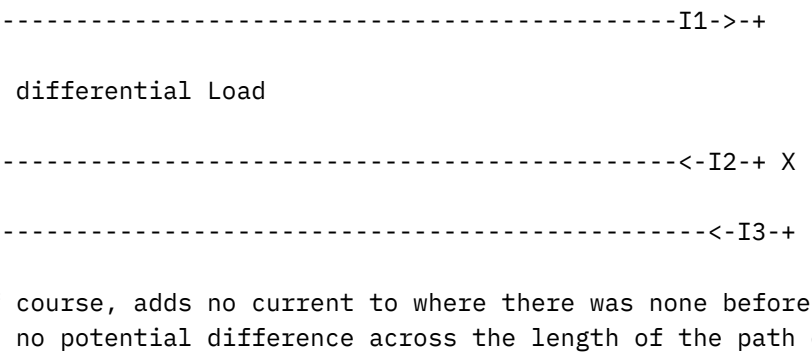
This came close as a description of the problems encountered in
discussion of the Common Mode. For one, I can appreciate the
inclusion of two sources as it mimics the actual circuit found in
nearly all of the HF rigs in use (at least for the transistorized
versions). This is a bit of a hedge in that the two sources are
actually a push-pull design, but the balance is already designed into
the rig and exists up to the final output transformer whose output
winding is fully isolated from ground - until it hits the low pass
output filter which ties one side to ground and the rig is unbalanced
(in the twin line sense) from that point on.

Your I3 circuit path illustrates one of the major oversights of the
earlier model this replaces. In that earlier piece, there was a lot
taken for granted (which is to say not illustrated) and it contained

outright errors (in correlation to the description of the circuit).
Again, consider:

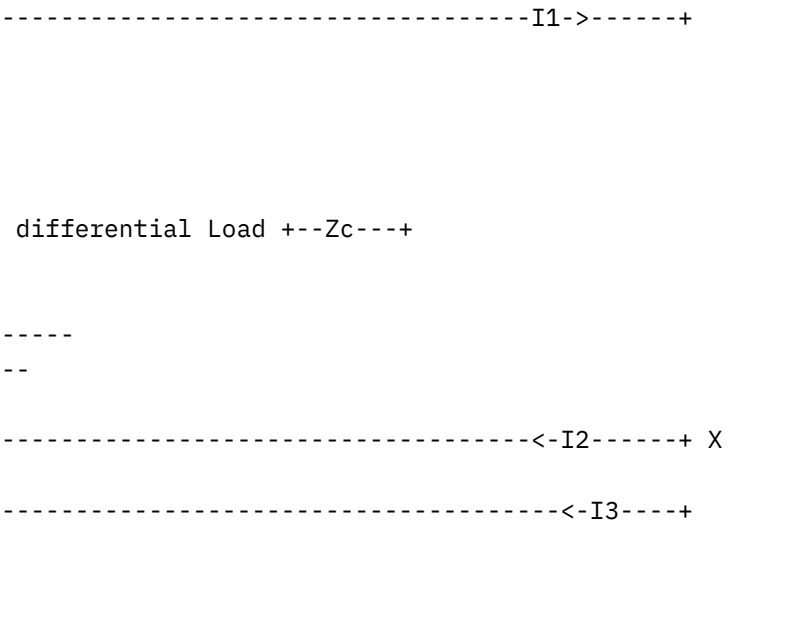


I3 as shown is wire going nowhere, it is unexcited and has no
reference (sink) to pass current to if it were excited. The
"presumption" is that it is the outside of the common shield. Even
this fails in the face of the obvious - the outside of the common
shield does not terminate in an open (which would make for a miracle
coax that had continuity on the inside, but none on the outside).
Rather, at a crude minimum it must look like this:



This, of course, adds no current to where there was none before as
there is no potential difference across the length of the path denoted
by I3. There is no current induced into I3 because the two currents
that could couple to it, I1 and I2, are equal and opposite as enforced
by the symmetry of the coax.

Continuing with modifications of the original, towards your design:



>> -

Take note that I add what is labeled Zc, which supplies the return
path for the Common Mode current.

The following perspective attempts to mimic the structure of a
balanced dipole fed in the middle with an unchoked coax. Z1 and Z2
illustrate each element of the dipole, are equal, and their electric
coupling to earth below is illustrated with *** paths through
reactances also equal (hence the "balance" with respect to geometry
and circuit elements). However, we have an additional path, that is
out of symmetry, which is illustrated as a metallic current path to
ground supporting an inductive reactance XL2.

```
------------Z1--------+ ++--------Z2-----------
* | || *
* | || *
* | || *
* | || *
* | || *
XC1 | |XL2 XC2
* | || *
* | || *
* | || *
* Source || *
* | || *
----- ------------- -----
--- ----------- ---
- --------- -
```

It matters little about the placement of the source as the feedline
imposes a condition of equal and opposite currents. As such it can be
replaced with a floating source as long as we retain the outside
shield path back to the original ground connection.
Which, when me remove the feedline:

```
------------Z1--------Source+--------Z2-----------
* | *
* | *
* | *
* | *
* | *
XC1 XL2 XC2
* | *
* | *
* | *
* | *
* | *
----- ------------- -----
--- ----------- ---
- --------- -
```

This reveals two loops of current from one source. It also shows the return paths for all currents. From this perspective, we can see that the source excites both the Differential and the Common Modes. We also see that the outside of the coax shield is in parallel with one element and its series path to ground. Hence, even though the model is physically symmetrical, the outside surface of the coax creates an electrical dis-symmetry.

This, then, answers all the questions I have offered:

Q1. Where is the Common Mode current I3 going?
A1. to ground (Common)

Q2. What is the potential that is forcing it?
A2.

$$\text{Source} * \frac{XL2 * (Z2 + XC2)}{XL2 + Z2 + XC2} \Big/ \left(Z1 + XC1 + \frac{XL2 * (Z2 + XC2)}{XL2 + Z2 + XC2}\right)$$

Q3. How does the Common Mode current return to its source?
A3. Through Common (of course), capacitive ground coupling to the radiating elements and then the Source.

Pretty good analogy, Richard. A flat-earth model is a model that doesn't match reality. A differential/common-mode model where the components are "NOT related" is a model that doesn't match reality.

There seems to be some people on this newsgroup who believe that when the model doesn't match reality then there is something wrong with reality. The preacher at my church has the same problem. :-)

Those are the SD-20 (West Bend - Sunny Day) fishing poles. They are great for backpacking and portable operations. My favorite portable antenna is two of those supporting a loaded 20m dipole on a rotatable mast. One is also used for the St. Louis Vertical. I've got plans to try two in a phased vertical configuration.

I see, a fishing pole, well that sounds better. I am gointo to connect two together with a piece of 2x2 or lucite or someting at the center then run an ordinary #18 wire along the length to form a dipole. I may use the pole itself as a form for two loading coils thus forming a 40 foot or so loaded and rotatable dipole. I can get it up to 50 feet which should help me make more east coast contacts. hanks for your input I'll check out the pole on the web. The World Radio ads are not too descriptive. I suppose they don't want you to know it's really a fishing pole.

Whoa there, Richard. I3 is NOT the current down the outside of the coax. I3 is the current flowing in a wire attached to a dummy load (or the current flowing in you if you are attached to the dummy load).

Even with a balanced source, a balanced transmission line, and a balanced load, hanging you (or a wire) off one side of the balanced load will result in I3. You can prove that to be an incorrect statement by grabbing one side of a dummy load being supplied with 1000 watts.

Sparks, W4EAS wrote:
"Sorry, You can NOT silver solder with propane!"

Glad I didn`t know that when I soldered all my copper water pipes using a propane torch. That was 30 years ago and they haven`t leaked yet.

I am no expert, but I`ve both brazed and soldered. I`ve done some welding too.

To get an expert opinion I searched the net. Department of Labor document came up first. It says:

Like welding, soldering and brazing use metal to join two pieces of metal but the added metal has a lower melting point than the workpieces.

Soldering uses metals with a melting point below 800 degrees Fahrenheit; brazing uses metals with a melting point above 800 degrees.
(Surely this refers to the added metals, not the workpieces.)

I am sure my experiences weren`t atypical. I recall that the copper pipes had to be dry to silver-solder, else the evaporation would cool the copper pipes faster than my propane torch could supply enough heat to melt the silver-solder. Dry copper conducts heat away fast enough to make the soldering no easy task. It would have been convenient to have had an acetylene torch, but propane was all I had and I succeeded.

Best regards, Richard Harrison, KB5WZI

> Sorry, You can NOT silver solder with propane! You use paste flux AND
> need the temp. of a acetylene torch! Regards Sparks W4EAS

Hmmm,

I have silver soldered various materials many times using only a simple propane torch. The only issue is the total amount of heat needed. The *temperature* of a propane torch is more than adequate. If the pieces being connected are massive (more than a few wires) then a larger torch will be necessary. In no case is the very high temperature of an oxy-acetylene torch beneficial.

Did I violate any laws by doing what I can NOT do?

Richard Clark wrote:
Q1. Where is the Common Mode current I3 going?
A1. to ground (Common)

I don`t try to follow the schematics as they are distorted in transmission and it`s too hard to figure what the author intended.

But, if you mean the common-mode signal is seeking ground, it has no particular reason to do so. The signal can`t escape the coax at the transmitter. There is no signal going to ground at the transmitter other than that which has made a round-trip inside the coax to the load then returned on the outside of the coax. It can`t exit the coax at the transmitter. The signal is not conducted through the metal there. Skin effect prohibits it.
Also, radiation from exposed antenna conductors falls on the ground, for what that`s worth.

Best regards, Richard Harrison, KB5WZI

From: Andreas Hofmann <andreash23@hotmail.com>
Message-ID: <3d34847b$1@news.microsoft.com>
Source record: 138503

Hi,

I am in the process of putting up a couple of dipoles parallel and will feed them with coax. Coax is preferable since I need to make it as invisible as possible, that is also the reason for putting up 2 or 3 parallel dipoles instread of a vertical or beam.

Now my question is, what about the balun? I know I need a balun, since the antenna is balanced and the coax is not.
I am actually thinking about putting a remote antenna tuner right on the antenna feed point. That way my coax losses are minized and it should perform just as good as a ladder line, I think. Will the antenna tuner act as a balun as well?

Any suggestions on how this can be done and on good 100 W remote tuners are welcome.

The guys doing my air conditioning work last week were using a small
propane-like torch to silver solder the copper pipes. I think they
were using MAPP gas instead of plain propane, though. :)

I used to silver solder small things using my normal soldering iron.

Several older radios do. Yaesu FT-4700, FT-470, FT-530, FT-5200, FT-5100, Icom IC-2340 and others. They do not do U - U or V- V , but will listen on one band while transmitting on the other. This is IDEAL (almost mandatory) for satellite use like UO-14, SO-41, and AO-27.

Sylvan Butler wrote:
> . . .
> I used to silver solder small things using my normal soldering iron.

People commonly confuse silver-loaded ordinary solder with "silver solder". Silver-loaded ordinary solder is ordinary tin-lead soft solder with 1 - 3% or so silver added. This is used for soldering surface mount components that have silver or gold metalization, or metalized ceramic terminal strips, to prevent wicking the metalization off the part. The melting point of this solder is only a little above the melting point of ordinary 63/37 or 60/40 solder. Ordinary flux and soldering irons are used to apply it. This is not what's usually referred to as silver solder.

Silver solder is a hard solder made from other metals than just tin and lead. Its melting point is much too high for an ordinary soldering iron, and it also requires a different flux than soft solder. Like several others posting here, I've successfully silver soldered small items with a propane torch, although some alloys might require higher temperatures.

Roy Lewallen, W7EL

I really didn't have practical transmitters in mind, but, rather, elemental voltage sources, each of which could be set to an arbitrary magnitude and phase, including zero volts. One of the rules about such sources is that they have zero self-impedance, so current continues to flow through them even if they are "turned off".

I just wanted to show the coupling mechanism between common-mode and differential-mode currents when the differential-mode circuit becomes unbalanced either in its sources or loads.

I think extending the analysis to real transmission lines connected to real antennas becomes difficult because circuit-theory conventions don't hold well for distributed components and radiative coupling. I snuck through on the unstated assumption that the velocity factor of the differential-mode transmission line was the same as that of the common-mode line. Otherwise I would have had to deal with W7EL's TDR "ghost".

Hi Jim,

The solutions are really quite simple. It is the experience of our
getting in the way of ourselves in confirming them that accounts for
the difficulty. Complexity is usually found in the problems we bring
to the solution.

Greeting,

Wondering if the LMR400 type coax works ok around a rotor, with several turns coil of course.

Have seen comments abouut 9913 solid center conductor breaking. Have had some up in use with UHF for almost 17 years. It's still ok, I think. :)

Anyway looking at new installation and new coax, for HF of course.

Thanks for any comment.

Regards,
Jim - KU5S

You may want to consider using corrugated drain pipe instead -- and get the kind with the weep holes in the bottom. The PVC is more expensive, harder to work with, smaller capacity and it WILL fill with water -- guaranteed unless the entire length slopes to a drain.

What I use is "Stay-Brite", available at any welding
supply shop. It is a eutectic alloy of 3.6% silver,
96.4% tin. It melts at 300C, as opposed to 63/37
tin/lead that melts at a little under 200C. I have
gone through at least 10 lbs of Stay-Brite in soldering
my 20 miles of radials. There is no flux in Stay-Brite.
Do not get flux at the welding store. What I use
is Kester R pure rosin. So far I have used half of
my 2 gallon bottle!

Can't help you about LMR400 specifically, but I do have some related
experience...

>Have seen comments abouut 9913 solid center conductor breaking. Have had
>some up in use with UHF for almost 17 years. It's still ok, I think. :)
>
As far as I've experienced and have heard of, the problems with 9913 or
its European near-equivalents (H100, Westflex) have been with tearing of
the outer conductor. What often happens is that, even though you have
left a generous loop, the whole loop rotates and the bending stress
still concentrates at the anchor points.

Depending on your operating habits, the shield could hold up for years -
or it could be only a few days if you got the installation wrong.

I never heard of a center conductor breaking - but maybe that's because
the outer always got there first.

>Anyway looking at new installation and new coax, for HF of course.
>
With any of these semi-flexible (= semi-rigid) cables, the rotator loop
is going to be a "consumable" item that you *will* need to change during
the lifetime of the installation.

To make the eventual tower-top job much easier, it's best to install an
inline coax connector near the top of the tower (but far enough down
that the rotation doesn't twist on the connector itself). Presumably you
have chosen LMR400 for low losses over a very long run - but since this
is only for the DC bands, why not change to RG213 near the top of the
tower? Then you can forget about the whole problem.

George I usually 95% agree with your posts but I gotta take
umbrage with this one. All loads whether "hoop", bending or shear
imposed on any mast or pipe generate stresses. Because all metals
are homogeneous and behave in a linear manner below their yield
points in all directions when stressed it is not possible for
a mast to "be stronger" when subjected to hoop loads than it is when
loaded to the same level of stress in bending or shear. To be
more specific it all actually gets down to compression, tension
and shear stresses which result from wherever they come from.
The fundamentally irrelevant external loading geometry.
Interstial slip planes and all that nonsense. Which don't
fly very high anyway in a NG dedicated to the eternal quest
for low SWRs and 12 DbD gains from wet noodles (without radials)
so I'll spare ya the rest of it. But it's out there.
>
>
Antenna masts are not subject to hoop loads so it gets down to
keeping the combination of the max. shear plus bending stresses
below the yield point of the particular recipe and heat-treating
of the steel (or aluninum) used for the mast. Plus a safety
factor.
>
>
Garden variety standard plumber's steel pipe is normally in
accordance with the specifications for ASTM A53 Grade 1
Schedule 40 pipe which calls for a well-known min. yield strength
of 30,000 psi. That's a structural design criteria any design
engineer can hang his hat and his beams on. Yes, "plumber's
pipe" is most decidedly a very widely used and accepted

structural material if used within in it's range of
allowable working stresses.
>
>
Malleabilty only matters when the structure is subject to
impact loads. Wind loads are not impact loads.
>
>
If the strength/weight ratio is a big issue it's time to pop
for masts made of steels like heat-treated ASI 4130, 4140 and
others of that ilk which have yields in the 75,000-125,000 psi
range. But you better have the coin to spend on a mast . . check
the Texas Towers website. Ugly! Plus shipping . . Not UPS.
But if ya need thinner walls to get the weight down the
higher strength steels are the way to go.
>
>
Me, I'm a cheap sumbitch, If the pipe is stamped "A53" it's gonna
work just fine *if* I plod thru the numbers and don't overstress
it. And I can get the stuff somewhere around the corner and
cartop it home.
>

I've done a lotta masts & other structures by the numbers as
explained in any applied mechanics 101 text, e.g., Den Hartog,
Timoshenko, etc. and with a lot of materials but I'd never
previously run into the specs for fence post stock so I called
around to several industrial & fence pipe distributors in this
area and asked.
>
>
There are *no* published mechanical specs for fence post stock.
There is zero quality control, accoutability or promises of
performance. Most fence post material is recyled junk steel
of unknown parentage, normally imported from God knows where.
Sorta like Radio Shack antenna masts . . . And this was from
the guys who sell the crap. If you wanna dangle your 13 element
Force 12 tribander at 80 feet from a fence post instead of from
A53 pipe be my guest George me boy . . or try to get a gas line
made from a fence post past your local code enforcement clods.

Perhaps I should have written "messy" rather than
"difficult". What I meant was that I wouldn't use
a SPICE-like program, with its lumped-component models,
to address an antenna problem where a reasonable
degree of accuracy is expected.

1285. Re: rempte antennna tuner as balun for multi-dipole antenna?

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-17 12:39:03 UTC
From: Don Niles <k2pmc@adelphia.net>
Message-ID: <HzdZ8.2318$Ga1.721542@news1.news.adelphia.net>
Source record: 138426

Andreas,

You mention parallel dipoles. If you mean you are using several dipoles, all connected to the same center insulator, you don't need a balun. I am assuming you will be using either 50 or 75 ohm coax. If you have a 40 meter dipole, you don't need a 15 meter dipole because at the 3rd harmonic, the 40 meter dipole will provide a reasonably low swr on 15 meters. On the other bands, the impedance/reactance will be sufficiently high so as to isolate the non-resonant dipoles from the resonant dipole. Your multiband coax fed system will work quite well.

Regards,

Don - K2PMC

Roy Lewallen wrote:
"I just want to make sure people understand there`s nothing about an antenna itself that makes its radiation characteristics different at resonance."

True enough. It`s current in the wire that in the right environment produces radiation.

In a standing-wave antenna, reactance in the wire inhibits current, Balance out reactance with its conjugate and lower the bar to current. When the net reactance is zero, the antenna is resonant.

The item some amateurs miss is: resonance isn`t necessarily an impedance match. A resonant 1/4-wave may look like a 30-ohm resistor to a 50-ohm coax, A mismatch exists between 30 and 50 ohms and SWR results.

Best regards, Richard Harrison, KB5WZI

1288. Minimum distance between mast mounted antennas?

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-17 13:23:01 UTC
From: Ed Laughery <laughery@bellsouth.net>
Message-ID: <U8eZ8.49867$1q2.3654578@e3500-atl2.usenetserver.com>
Source record: 138428

Hi

What is the minimum distance to keep between a 6 meter yagi and a 2 meter yagi on the same mast? Is this a rule of thumb or is there a formula to compute this data? If the 6M yagi were replaced with a 6M 1/4 wave ground plane (with four 1/4 wave radials), would the distance between be effected? In a more general case, where HF and 2M and/or 6M antennas are placed near each other, does the same rule or formula for minimum distance between apply? If not, please elaborate.

I am currently trying to weave my way thru EZNEC - do the above questions lend themselves for modeling to obtain a solution?.

Thanks in advance.

CW,

You may call it silver "brazing", but I choose to call it silver "soldering". In any case I am talking about stuff like Easy-Flo, not Radio Shack 2% silver bearing lead-tin solder.

Another of my hobbies is model engineering, in which silver soldering (brazing) is widely used. The great majority of folks use the term silver SOLDER.

(Even the Brits, Reg. I have dozens of model engineering books by British authors who use the term silver solder.)

Perhaps someone can check with the IEEE dictionary. 8-)

Reg, G4FGQ wrote:
"The whole system must, must, must be resonant."

A little exaggeration for emphasis and illustration, perhaps. There is some truth in there, somewhere.

If the standing wave antenna is not resonant, its reactance may allow little antenna current.

"Antenna tuners" at the operating position can resonate the antenna via the transmission line, so the antenna current is maximized.

Best regards, Richard Harrison, KB5WZI

I did another net search on "brazing rod". The first item:
#3111 Silver Solder Rods and Flux---Melting temperature 1300 degrees F
and external flux is required.

By the US Dept. of Labor definition, these rods would qualify as
"brazing" as more than 800 degrees F temperature is required to melt
them.

This worked for me,,,,,,,,,,, because I live 'out in the boonies'. Sometime back I noticed the High Way Dept taking out some damaged sign poles, you know like STOP, SLOW, Curve,, and the like,,, well since they were close to my home, I decided to ask them what they were going to do with the 'poles'. (6 foot tall, not counting what was in the ground) The told me they were replacing the fiberglass 'poles' with metal,(I had never noticed, or knew they were fiberglass) soooo, on the upbeat I told them I was a ham and could use a couple of the "masts". I figured they would tell me where , and when I could buy or put in a bid for the poles,,, I have bought 'pipe poles' from junk dealers in the past, who had bought pipe from the Hi Dept but in bulk. To my surprise they said they would drop off the fiber poles at my house since I lived just a few blocks away....,So that is something to consider next time you see those guys out there with the reflected jackets working on signs. just my two cents. cl.

yes, kind of... old so-239's with cheap plastic or phenolic insulation can break down with age or heat. the capacitors are probably a ceramic type so they would probably not degrade with time, but could be damaged by shock, lightning, or too much power. check it by putting it between an swr meter and dummy load, it should not appreciably increase the swr on the hf bands. if you have a 6m or 2m transmitter you can try those to see if it does show some rejection above hf or take it to a local tv or radio repair place and see if they have a sweep generator to test it with.

Ed,
I don't know of any 'hard and fast' rule about
antenna separations. In general, you want to keep
them as far apart as possible, or within reason.
Usually a 1/4 wave separation is the 'rule of thumb'.
With 6 and 2 meter antennas, I'd use at least a 1/4
wave or about 2 feet separation, more is better.
A 1/4 wave at the higher frequency of the two, sort of.
I wouldn't replace the 6 meter yagi with a grondplane
unless you just wanted too.
The same holds true for HF antennas, but is certainly
harder to do. You usually have to settle for some
'reasonable' distance, rather than a 1/4 wave. The
higher frequency antenna is affected more than the lower
frequency antenna, but both will be affected to some
extent. (Don't you just love these definite answers?)

Thanks for the info Doc

Of course, every answer generates a couple of questions, so here goes....

Does the inevitable effect of the antennas near each other cause changes in resonant frequency and/or radiation pattern?

Look forward to your response - definitive or not (Hi).

1314. Re: Help building 23cms loop yagi

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-17 22:25:55 UTC
From: k0bg@aol.com
Message-ID: <20020717182555.01969.00000256@mb-mr.aol.com>
Source record: 138454

There are several posted plans for loop yagis for 1296. But....

Most of these are NOT ATV types. At 1296, the band width of a typical yagi is a little shy of what is needed to ATV, and way shy on 435.5.

When you find one, you need to make sure the design is for a LARGE driven element(1" or more), and/or one with a loop driven element. Having once been on both 435.5 with 12, 22 element yagis and 1296 with 24, 32 element yagis, band width is an essential element if you'll excuse the pun.

1315. Re: rempte antennna tuner as balun for multi-dipole antenna?

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-17 22:37:18 UTC
From: k0bg@aol.com
Message-ID: <20020717183718.01969.00000259@mb-mr.aol.com>
Source record: 138455

There are lots of folks on the newsgroup who will disagree, but you really don't need a balun. Yes, they are nice to make sure there are no parallel currents on the outside of the coax, and as a 'cure' to skewing the pattern of the dipole. But not a necessity. If you use a tuner, and you decide to use a balun, you'll almost have to make one. Most purchased baluns do not do well with high VSWR, especially those made with ferrites. A better choice is an iron cored one, like a T200-2. Properly made, they'll handle very high VSWR without damage.

You can purchase from ARRL Dr. Jerry Sevick's "Building and Using Baluns and Ununs". It is the bible on baluns.

There is a difference between silver brazing and silver soldering. Brazing
is done at a much higher temperature than soldering. As Richard pointed out
earlier, the excepted cutoff point is 800 degrees. In both cases, silver
bearing allow is used as the filler metal. Alloyed differently for the
temperatures involved. It has nothing to do with what you choose to call it.

1317. Attic loop question

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-18 00:51:07 UTC
From: Frank Helsell <fhelsell@mchsi.com>
Message-ID: <_hoZ8.569967$cQ3.53535@sccrnsc01>
Source record: 138458

I am installing a wire loop in my attic. I can install it vertically (7 feet high and 50 feet long) or horizontal (12 feet wide and 50 feet long). I would appreciate hearing anyone's opinion on whether it would be better to install the loop vertically of horizontally.

Some additional info, if it will help:
I will be feeding the loop with an SGC 237 auto-tune coupler.
I hope to use it on 80 meters through 10 meters.
Almost all of my QSOs are stateside CW ragchews - I don't do much DX.
I'm running 100 watts.

73,
Frank Helsell
W&#65533;MHZ

what is a good antenna to use for frequencies 1-30 mhz

1319. Question on antenna separation distance

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-18 01:12:46 UTC
From: tek_guy@hotmail.com
Message-ID: <cbf4a67d.0207171712.4614d06c@posting.google.com>
Source record: 138460

I've just installed a new antenna for 6 meters (a Par Omniangle loop), and I think I've run into a problem with antenna separation. The radio is an Icom '706MKIIG, if that makes any difference.

The antennas are up in my attic (more of a loft, really). The Par is on a 4 foot high mast on top of a metal shelf unit. Before, I stuck a mag-mount antenna on the metal shelf for an FM antenna. But now, that shelf is in the footprint of the loop.

I've read posts on how 706 owners have damaged the radio's front end by having antennas too close. Ideally, I'd like to run 100 watts on the 6 meter antenna, and have the option of 50 watts on the mag-mount. I usually use somewhere around 10-25 watts for repeater stuff, but I'd like to be able to run full power if I ever need to...

My question is, how far apart should I have these antennas, so I don't overload the radio's front end?

Thanks in advance.

Jim, KG4NEL

Ed Laughery wrote:
"Does it matter which antenna is on top?"

Usually not much advantage or disadvantage from which antenna is on top. Bragging rights are "important" to some commercial users so that multiple-user towers are often equipped with candelabra mounts to place antennas at the same height, though this may severely increase the amount of each others energy they each have to deall with.

Which of your line-of-sight paths is most critical to you? You might put that antenna on top.

Coupling is much greater between parallel wires than end-to-end wires. One VHF repeater manual estimates the difference is 10x. I haven`t verified the claim. End-to-end wires have each other in their nulls.

One vertical antenna and one horizontal antenna re pretty well decoupled. Cross-polarization loss is often estimated around 20 db.

The path loss in a transmitted signal is 22 db in the first wavelength traveled plus 6 additional db loss every time the distance doubles after that. You can pick the isolation you want from physical separation from that.

Many multiple antenna users are satisfied with several wavelengths separation. This usually gets you out of the near field.

For diversity reception, 10 wavelengths has been found to provide signals which usually fade independently. At microwave frequencies the separations used are usually greater. You often see the dishes separated by tens of feet and the frequency is 6 GHz. Go figure.

At the lower frequency, an antenna is fewer wavelengths above ground than an antenna operating at a higher frequency. To equalize the playing field, you might put the lower-frequency antenna on top.

In stacking antennas, you might recall that 1/4-wave from a reflecting surface tends to reinforce the reflected return combined with the incident perpendicular to the reflection surface. The round trip is 180 degrees. The reflection process adds 180 degrees, and this puts the signals in-phase directly back at the origin. An example is the horizontal antenna 1/4-wave above earth. This antenna is a noted cloud-warmer. An elevation of 1/2-wave by the same logic cancels the signal directly overhead.

Best regards, Richard Harrison, KB5WZI

Jim KG4NEL wrote:
"---how far apart should I have these antennas, so I don`t overload the radio`s front end/"

This is best determined by experimentation. An example. UHF STL links were to be replaced by VHF (100 MHz FM broadcast band sets) to reduce fades and improve fidelity of our programs. Problem! Broadcast shortwave signals overloaded the FM receivers and SW harmonics also plagued the STL reception. This problem should have been anticipated, but it wasn`t.

Solution, a sweet spot was found about 1/2 mile from the transmitting plant for the 10 STL receivers and their corner reflector antennas.

Jim might find a sweet spot for one of his antennas before he destroys a radio.

Best regards, Richard Harrison, KB5WZI

Try a random length of wire as high and as long as you can make it. You may form it into a loop surrounding your property and connect it to the aerial and earth terminals of your radio. You may make a more compact loop of wire for indoor use.

Reg G4FGQ, may have a free loop program and may be asked for suggestions.

My new RCA K-80 all-band console came with an internal large rotatable loop with a few turns of good sized wire that seemed to work well on all bands and that was over 60 years ago.

Best regards, Richard Harrison, KB5WZI

CW,

You can call it what you like. I choose to call it silver solder.

The stuff I typically use has a melting temperature in the range of 1200 F to 1300 F. The material is sold as silver solder, and that is a very common terminology.

An example of usage by one of the worldwide leaders in the field is taken directly from the Johnson Matthey web site.

"Johnson Matthey's Silver-flo range forms a group of more than 20 cadmium free silver brazing alloys. These silver solders have been developed to meet the brazing needs of all sectors of industry."

It would seem that both terms are used somewhat interchangeably.

Feel free to bask in your "correctness". I am over and out on this topic.

And, by the way, the original issue was the need for an acetylene torch to work with these joining materials. I have silver soldered (brazed) many times without ever once using an acetylene torch to do so.

Whomever it was that wanted to connect radials to a wire ring around the base of his antenna should go ahead and use whatever torch he has available.

73,
Gene
W4SZ

Hi there,
I am looking for a small (2-3 feet tall)for my attic,dual band base antenna?
Any ideas of what works well? name and or model?
What the price is?
Any gain?
Please e-mail me directly with any info???...
rusty@dccnet.com
Thanks very much-Russ

1325. Placement of egg insulators?

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-18 06:40:20 UTC
From: post_to_usenet@hotmail.com
Message-ID: <b6b4e772.0207172240.170dd584@posting.google.com>
Source record: 138467

Hi,

We will be installing a GAP Eagle at the local radioclub and some of us wonder on what is the best placement of the egg insulators on the supporting wires.

At first I thought it would be good to have the first set of them at 2.5m (8.2 ft) from the mast as this is a quarter wave of the higher band to use (10m).

Then thought that this is probably not what we want to do. I assume that for a vertical dipole type antenna what you want is a mast NOT resonating on the used frequencies so that it presents a high impedance and the field is affected as little as possible.

Please explain or direct me to some online info on these questions.

Thanks in advance

Toni

1326. Harmonic generation on supporting wires?

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-18 06:48:48 UTC
From: post_to_usenet@hotmail.com
Message-ID: <b6b4e772.0207172248.744dc7f1@posting.google.com>
Source record: 138468

Hi all,

Can the supporting wires, directly attached to the antenna's mast, act as harmonic radiation generators due to rectification in the (likely to get rusty) wire-mast union?

I assume this could happen when the supporting wires are resonant on the used frequency and important currents developed in the wire-mast union.

Opinions?

Thanks for answers

Toni

In principle, the loop enclosing the largest area is the most efficient. On the other hand a small loop is best in the vertical plane.

Just try both and see what happens.

1331. Re: rempte antennna tuner as balun for multi-dipole antenna?

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-18 09:31:21 UTC

Source record: 138372

Multi-band dipoles:

I would agree with the prior posts here. Balun not necessary. And I would go one step further and propose that with proper antenna lengths and proper coax feedline lengths, you will probably be able to get away with having your tuner at the transmitter end of the coax vs at the antenna end, much simpler. I would certainly recommend trying it that way before you go to the extra work. I am using two such multi-band antennas, (parallel dipoles, in the same cable, 3 dipoles per band, fed with coax, tuner at the transmitter end). I use them on 40, 30, 20, 17, 15, 12 and 10 meters.

I am looking to replace my mobile antenna and am looking for
advice/opinions/suggestions on what you believe is the best mobile antenna.

It must meet the basic requirements:

*best gain/performance/reception
*must be magnet mount of some kind due to having to move it from vehicle to
vehicle and
cannot drill in either vehicles.
*must be at least a 2 meter antenna, but a dual band would be cool.... 6m/2m
or
70cm/2m. Even a triband would be cool if the gain was decent at least on
6 and 2
meters.
*Under $125 bucks.

Lemme know what your suggestions are. My current J*p Shack antenna has
definitely seen better days and needs replacement.

(good antenna for 1-30 MHz)

That is correct, but there are usable wide-range antennas. Many military and commercial radios have been supplied with a whip or wire to use over the entire range. These generally are end-fed from a very versatile tuner.

I'm not a sailor, but I have a good friend who is. He has a 75 foot cat. We installed insulators in the main mast portside backstay which is about 65 or so feet in length. This is fed by an Icom AT-130E (maritime version of the AH-4) located near the port keel groundplate in the Captain's cabin. It feeds the stay thru about 12 feet of RG8 grounded only at the tuner end. It easily covers 80 thru 10, plus the 2.1 Mhz emergency calling channel.

Toni:
Yes.

Which is why many people put egg insulators in them on the top end next to the mast. And break them up in pieces smaller than a half wave on the highest frequency of interest. It depends on many variables, primarily how much the antenna is coupled to them. By the way, they are commonly referred to as guy wires.

Good Luck!

Providing you don't have any squirrels around. I had one shred a length of
that rope for lining for its nest. Ruined a 100 foot piece of it right in
the middle which I was using for a halyard. They don't seem to bother
Phyllistran (or is it Phillystran?).

On the other hand, you could use one properly selected antenna with openwire feed. The diameter of such wires is a lot smaller and thus harder to see. If you use transparent tubing or polystyrene separators and an insulated wire of a "blending" color, you will get few complaints. Then tune your feeder and antenna to the bands
you want to use.

1350. What antenna do you use as SWLer?

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-18 17:57:18 UTC
From: mail2michelnl@yahoo.com
Message-ID: <3d37009c.522870@news.sprenkeler.myweb.nl>
Source record: 138392

Hay folks,

For SWLers I have a question. Since a half year now I own a 535 what I always wanted because it is (was?545) the best non commercial hf receiver.

One question I have for you SWLers is what antenna do you folks use on

your receiver? As curious I am I wondering why you use that antenna in what circumstances.
For example: I use my 535 with 16 meters wire (stainless steel 0.7mm) on a RF Systems Magnetic long wire balun (MLB) in western Europe (Netherlands). Till now I didn't find a antenna with this length that can deliver more or better signal. A next step is perhaps a T2FD (low noise antenna) because the S/N ratio is better.

In short: What kind of antenna do you use with your receiver, why and in what circumstances.
I'm sure other SWL'ers are curious about this.

gr. Michel

1351. Re: impostor a solta

Hyioqt@lassa.com warns us of an "impostor on the loose".

We are further advised of a professional certified psychologist`s opinion about the "real" personality of Leonardo Paredes (Mr Walls?).

The author of this tirade goes on to say he doesn`t know, or know how to say, "Leonardo", but the description all corresponds to a disturbed personality.

This is supposed to be an expert opinion but as posted on this newsgroup, it is hear-say at least twice removed. Further, no connection to antennas is claimed. So, I don`t think it belongs here.

Best regards, Richard Harrison, KB5WZI

William Piccione wrote:
"Also is it possible to trail an antenna in the water?"

The sea short-circuits horizontally polarized waves. Vertically polarized waves are reflected in-phase with the surface wave. If you want DX, use vertical polarization.

I used a slate blue/gray - one of the Rustoleum brand of accent
colors. It's somewhat darker (I think) than the "smoke" color, but
works as a pretty good "not too awfully visible against the sky"
shade, and it's close enough to the colors used on our house walls and
trim that it fits in well.

Richard,
You're right, the military and a few manufacturers have fixed length antennas that can be used over a very wide frequency range. Even so, the performance on the lower bands is pretty crummy. The key work in your post was -tuner-. With a tuner that's versatile enough, you can make a 9 foot whip work anywhere. But not very well in most places. There still ain't no such thing as a free lunch...

Hi,

You could try a trailing counterpoise though if your hull is fibre-glass or some such material. Years ago I was involved in fitting radios to police boats on an African lake (Malawi) and we couldn't get a decent ground for that reason. Efficiency went up hugely just by trailing a wire even though it was in fresh water. We were very careful not to get it anywhere near the props though.

Cheers - Joe, G3LLV

Right. And many soldering irons will heat above 800F. This
distincting between soldering and brazing seems to be a frequent
topic of conversation in the rec.crafts.metalworking (IIRC) group.

> bearing allow is used as the filler metal. Alloyed differently for the
> temperatures involved. It has nothing to do with what you choose to call it.

Pretty much. I don't know how long the 800F distinction has been
made in the various parts of the world though.

The other issues people may have, is that you can find a wide range
of melting temperatures in silver alloy filler material for
soldering or brazing. If someone uses an 800F liquidity alloy with
a soldering iron, is that soldering or brazing? When someone uses a
900F allow with MAPP gas that is brazing, but someone who has only
used a 1200F alloy wonders how anyone does silver brazing without an
OxyAcetylene torch. (Sometimes slow heat is good enough, other
times you want quick heat to avoid spreading heat too far thru the
assembly which can damage the valve, or dis-temper the barrel, etc.)

The MFJ-1724B is a great starter antenna, both me and my XYL used them when we first got licensed last year. In fact, she is still using hers! I have since upgraded to a Hustler 5/8 wave mag mount that set me back about $35. It offers a noticeable performance improvement over the MFJ and the price didn't break my bank.

Tazanator,
I think that if you check, you will find that
the antenna that submarines 'trail' is used on ELF.
Anything above ELF is sent using a multipurpose
antenna usually built into the periscope. I'm afraid
that an HF antenna 'trailed' through the water makes
for one terrible signal.

Hi Michel,

You name two antennas amateurs would not pick normally - loss being
the key factor. For reception, it doesn't matter too much as you can
always add gain (once you have a signal).

Aside from your choices, for SWLing, I have always found a long-wire
is as effective as any. As high and as long as possible. Once, you
have that, more important choices are in tuner or preselector.

RG = Radio Guide
U = General Utility

You will find the /U suffix on many US military nomenclatured items which can be applied to more than 1 specific system. Sometimes, like coaxial cable, it applies to almost all systems. It also appears as the first letter in AN/xxx nomenclatured systems, as AN/URD-10.

By the way, the RG nomenclature system is obsolete, and replaced by M17/nn-nnnn numbers. See MIL-C-17 for further information.

Hello:

I now have in stock a Tape Whip Adapter that accepts 5/16-24 male threaded antennas (like are used on the PRC-25 and PRC-77) many of which are available on eBay at a reasonable price and screws into standard ham radio 3/8-24 antenna bases. More info at: <http://www.pacificsites.com/~brooke/TWA.shtml>

Hi Michel,
I too have to agree with Rick, as I was a serious SWL'er prior to getting my ham ticket. I used a simple "long-wire" about 75 feet long up about 35 feet and could easily tune to just about any station provided conditions of the band were good. It was a cheap and effective antenna. If you get plagued with noise, add an outboard DSP unit to your rig (Timebridge, etc) and it will clean-up your signal quite a bit.

Best of DX and 73,
Scott - W3BUG

Can't say about the price, because its been some time since I bought
mine (maybe 5 years?) but the Larsen dual band 2m / 440 antenna on a
Larsen mag mount, right in the center of the roof, is a really good
working antenna. Built like a tank, it has a magnet that is good for
really high speeds, too, so if you are on I-10 in Arizona, where the
limit is 75 and everyone goes faster-than-that, it still won't blow
off even in a stiff headwind. Well, usually, anyway! <G>

I've been using Larsen since I was a 2-way radio tech some 22 years
ago, and converted to Larsen from Antenna Specialists because they
did blow off the top of my car, and have found them to always work
very well.

What are the disadvantages of a j-pole antenna made of copper tubing? Is any ground plane needed. If not why not? What are the best books to read or websites about j-pole antennas, more specifically cooper tubing j-poles. How would an vertical antenna (commercially made from Diamond, Comet, Hustler, Hy-Gain, ect.)with ground radials compare to a j-pole antenna for 6m, 2m, 220MHz, 440MHz, and 1.2 GHz? What would most of you use?

Michel wrote:
"A next step is perhaps a T2FD (low noise antenna) because the S/N ratio is better."

I agree with Ricard Clark. The value of the T2FD is in its ability to quickly and easily accept transmitted frequency changes without fuss. For reception this is not a problem.

It`s true the noise s lower but so is the signal especially in the Netherlands where soil conductivity is excellent. High soil conducivity short-circuits low-angle horizontally polarized waves.

As an SWLer, you want to hear from many directions. You want to hear from near and far. A vertically polarized antenna is ideal for your situation.

Use the tallest wire you can erect. You can add a flat-top to it for capacitance loading, or make an inverted "L". Use this vertically polarized antenna against a good connection to that excellent Dutch earth. Enjoy!

Best regards, Richard Harrison, KB5WZI

A J-Pole has approximately the same current distribution as a center-fed
1/2WL dipole. It is simply end-fed with a matching stub. Up in the air,
like the center-fed dipole, it needs no ground plane, but maybe does
need some decoupling like a few turns of coax acting like a choke.

Yes, I've used stainless steel cable (tower guys) for HF antennas successfully
for years. There will be some (minor) loss compared to copper but it works well.

> Also is it possible to trail an antenna in the water?

Nope. Under way, the water is your "ground". :-)

Dunno...When I hear the term "low noise" used for an antenna, my first
thought is "low performance". Noise is rf just like any other source.
If your antenna does not receive noise too well, it's likely not going
to be too hot on the desired signals tuned. Many antennas are "quiet"
due to excess loss in the system.
>

> In short: What kind of antenna do you use with your receiver, why and
> in what circumstances.
> I'm sure other SWL'ers are curious about this.

Myself, I use the same antennas I use on the ham bands. Most HF stuff
is received on my parallel 80-40-20 meter dipoles on a single coax
feed. In the winter, I often change it to 160-80-40. My 160m inv L is
also usable on most any HF freq. I have other verticals I use from
time to time. I use verticals and yagi's on VHF/UHF. I've recently
built a few small loops for lowband receiving. I can use those or my
wire antennas on those bands, but I get less AM-BC trash on the loops.
I'm in a hot AM-BC area, with good ground conductivity, and much
moisture. It's easy to have problems due to rectification in corroded
metal. I've been having a problem with that on my wire antennas if
used on longwave or even 160m. For some reason, my house, mast or
both are overly hot with AM-BC rf. I haven't been able to cure it yet.
I've tried unhooking guy wires, grounds and ungrounding, coax changes,
banging my mast for static ,etc, etc, etc, and still haven't nailed it
down. I notice my water heater is real hot with AM-BC rf also...And it
came about fairly gradually over a period of months and seems to be

getting slowly worse. I can get on my ladder line fed 40 meter dipole that is in the attic, and the noise is gone for the most part, but the tuner may be helping on that. And the two antennas are not that far apart. You would think the attic antenna would be worse, being close to the plumbing, etc, but not so. I heard one guy mention problems like this just from using stranded copper wire for antennas. It happens that all my antennas are stranded wire, but they do have the insulation on them. So really , you wouldn't think it would be a problem. My attic antenna is using the same wire, and it's not as bad. The thing is, using a portable am radio as a FS meter, it seems my mast, and the grounded metal around the house are the hot points, not my antenna itself. IE: the ground wire to the power line coming from the pole is pretty hot also..
I'm getting a lot more local AM garbage on the low bands than I did a couple of years ago. Something has changed around here, and I'm gonna have to find what it is.
BTW, using a tuner or even just a variable cap inline kills a lot of it, but I shouldn't have to do that. MK

You can use a propane torch to do that as long as the area is not too
big.
The problem with many small propane torches is they don't have the
heat needed to really do it up right. You end up with crappy looking
and weak joints. With an oxi-acetylene torch you have the heat needed
to really have the solder flow well. Makes much smoother and stronger
joints when the solder is flowing like hot butter. I've got an
oxi-acetylene torch here in the room with me. "anti-theft measure"...I
do A/C work at times, so always have one. But I also keep a small
propane torch on my truck as a emergency backup. Never know when I
might want to burn something...But I have to say, I consider the
propane torch a "toy" in comparison to the oxi-acetylene torch. It
just barely gets enough heat going to do the job. Ok for small stuff,
but not large. I can burn up anything with my trusty oxi-acetylene
torch. Give me a little time, and I could cut a car in half. :) MK

I'm about to mount a HF vertical with a counterpoise on the roof. The antenna will be mounted on a steel tube and the tube will be led through the roof and supported on the attic floor.

Should the steel tube be DC-grounded to the house' ground system to protect against static electricity and lightning? Or should it not - to avoid lightning stroke? (E.g. that the antenna would be more 'attractive' to lightning because of its low potential relative to the air).

Should the tube be RF-insulated from DC-ground?

Henrik,

It probably doesn't matter either way but I would
suggest grounding it.

I had a Cushcraft vertical mounted on a steel mast
outside the building with my hamshack. The steel
mast was sitting on the ground and tied to a copper
ground rod. The antenna took an induced lightning
hit sufficient to blow the balun box into small pieces
and deform the traps. The lightning travelled down
the coax taped to the steel mast and then burned
a small hole in the roof where the coax first touched
the roof en route to the window where the cables
come in. I had a coax feed-thru bushing mounted
in a grounded aluminum panel at the window. The
center insulation was burned out of the coax connector
leading to the rig.....an FT-990 that became a parts
unit in a real hurry. In addition, a telephone company
connection box outside the house was blown apart,
and, where my long wire antenna lead-in laid against
some wood trim, the wood was shattered as though
it had been ripped up with a pry bar.

In short, lightning does what it wants and there is not
much one can do....

The commercial antennas may be colinear, so they offer extra gain by compressing the elevation lobe. Nice looking, sturdy, and multiband (eg. three bands of 50 (limited), 144, 432, 1296), I'd certainly use them, and I've seen that many who do.

The ARRL Antenna Handbook offers two designs for J-poles, but there are several descriptions on the net too, including a variant using the TV style ladder line (this is said to work even up to 1 GHz). I remember one multiband description, 144/432 j-pole cactus antenna of copper pipe :) One link is http://archimedes.galilei.com/raiar/cactus.html another site I have had the honour to visit is http://hamgate1.sunyerie.edu/races/antenna.htm

Do you have building codes that should be followed?

It does matter. The question is not whether it should be grounded,
but HOW.

>In short, lightning does what it wants and there is not
>much one can do....

But there is a lot you can do to help eliminate the problem.

Here are some suggestions:

First, how is your house grounded? Find that grounding point where
the electrical system meets the ground. Take a separate ground wire
from that very grounding rod (or cold water pipe if you live in an old
house) and ground your antenna system to it.

Second, that ground wire should be as straight as possible.
Straighter is better because it means less inductance.

Third, don't go cheap on this wire. Make sure it's at least #10 AWG
Solid Copper wire.

Fourth, if at all possible, stay away from electrical lines or the
interior of the house, but keep the wire straight.

The idea is to ground everything at one point and have everything in
the house ride that one ground point up and down in potential. You
want Minimal inductance on the wire, and if possible, try to keep it
from inducing currents in other wires nearby.

I've seen grounding like this work very well at work. Our towers have
taken direct lightning hits and our equipment has suffered absolutely
no damage.

Hello CAM,

No, the building codes does not contain any paragraphs about antennas.
My (former) neighbour mounted a CB antenna on the same roof in much the same
manner as I explained. He did not ground the tube.

Henrik,
Anytime you 'bring' RF into your house, or closer to your electrical wiring, you increase the chance of having RFI and electrical safety problems. The 'idea' is to minimize any interaction as much as possible.
The metal tube/pole is more a safety issue than an RF issue. Grounding the pole from the attic, and avoiding interaction with the house wiring, can turn into a major undertaking, but one that I would certainly do the best I could with. Exchanging the metal tube for a nonconducting one would be what I would rather do, but that that may not be an option for you.
I would ground the metal tube from the roof before entering the house, using the largest conductor I could find (or afford). Providing a path to ground before entering the house is preferable to going 'through' the house, if possible.
I hope this helps...
'Doc

After hearing horror stories about birds being blown to bits by lightning
hitting birdhouses, I have installed my birdhouse on a fiberglass pole.
I also use fiberglass poles for my dipole antennas and 2x4 wooden supports
for my vertical.

Mark Keith wrote:
"My 160m inv L is also usable on most any HF frequency.---but I get less AM BC trash on the loops (for lowband receiving)."

This is information Michel can probably use. The "L" has very little directivity but the loop has nulls.

The vertical antenna is poor from a noise standpoint as it receives from all azimuths and most noise is local and vertically polarized. There is no groundwave propagation of horizontally polarized waves.

The vertical traits that make it susceptible to noise also make it susceptible to signals. In The Netherlands, making a good ground connection should be easy and a poor ground connection is the reason verticals don`t give good performance in many places.

The horizontal antenna would have to be impractically high to work well for many SWLers in a country with such high soil conductivity as many places in the netherlands.

Best regards, Richard Harrison, KB5WZI

Hi Henrik,
I'm no expert in lightning protection, this is my personal opinion:
I would connect the mast (steel tube) to a low-impedance ground, but NOT via the inside of the house. If your house already has a lightning protection system with proper grounding, connect the mast with a thick, short wire to that. If it has not, you had better install it before erecting the antenna or make a "lightning ground" at least. An occassional lightning stroke must be caught BEFORE it enters the house, if you want to prevent a REALLY BIG fire.
Remember, a lightning is a high-energy RF process, so both low resistance and low inductance are essential.
Another question is protection of the antenna radiator. It cannot be grounded directly, of course. Use a gas discharger between the coax and protective ground, just at the bottom of the antenna. Bridge it with a several kiloohm resistor to bleed the static. Use a transformer separator in the coax. If you do not use the antenna or when a storm approaches, the best solution seems to be to physically disconnect the coax outside (before it enters your shack) and connect the antenna lead directly to ground.

Thanks for all the interesting comments and suggestions.
The building has no lightning protection system (but I'm afraid my antenna
is going to be...)
but the ground system is new. Because my shack is in the attic (close to the
antenna mast tube)
about 40 feet above the ground point (where the ground wire is connected to
physical ground/water innlet). But the wire is thick (I think #10) and is
accessible
about 15 feet away from the antenna.

Henrik

That would be fine if you could exchange your antenna and line for non-conducting items. You can`t. So, use a conducting mast and if you can`t, use a heavy ground conductor for the length of the mast by all means.

I have been investigating vertical antennas. Now that I have looked at 5 different antennas I am confused as which one to purchase.

I am leaning toward the Cushcraft MA5V. Said vertical antenna will be mounted on a 30' tower and fed with 1/4" hard line.

Which one would you fellow hams like to suggest?

1409. Horizontal DELTA and SQUARE loops (EZNEC DEMO) question

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-19 16:08:02 UTC
From: ardujenski@aol.com
Message-ID: <20020719120802.26819.00000021@mb-bg.aol.com>
Source record: 138350

I am a bit new to use of EZNEC (DEMO) but slowly learning the ropes. I playing with 80m horizontal loop at 30ft high I got an interesting result. The 80m DELTA seemed to exhibit a few desireable features (for me):
(1) No null at high angles as with SQUARE
(2) More uniform pattern and fewer deep nulls as you go up in frequency/band
(3) No real directional or predominate lobe

I was comparing the 72ft per side SQUARE to a DELTA 96ft per side both at 30ft.

I know I have limited number of elements but has anyone else had similar results? Alan KB7MBI

Ivan, OK1SP expressed many good observations. Ivan also wrote: "Use a gas discharger between the coax and protective ground,---."

The coax exterior needs to be grounded directly at the base of the tower, unless the tower is base insulated.

Gas dischargers may be obsolete as differential-mode protection across coax. Many radios are solid-state now, and not able to take the energy that could get by before the gas tube fired. They are too slow and require too many volts to ignite for most solid-state.

Fortunately, coax discriminates against the common-mode which lightning imposes on the coax interior. The coax interior is a natural common-mode choke. Lightning is going to travel on the coax exterior, not its interior.

I worked many years for a company with 100`s of radios in many places and we had zero lightning damage on radio inputs and outputs. We also had zero gas tubes on antenna circuits. I believe gas tubes are superfluous on most antenna circuits. I have used many gas tubes on low-frequency circuits. They protected well and were less troublesome on audio circuits than the carbon gaps they replaced.

Best regards, Richard Harrison, KB5WZI

1411. Pro57B on a Hygain Hg-52 tower

Richard,
The point of not using a conductive mast is that
you decrease the number of contact points between
mast and structure. Those points of contact provide
a nice source of 'fuel' in case of a lightning strike.
Eliminating those points of contact makes your local
fire department happier too.
I know of one or two operators that I wish did use
non-conducting antennas and feed lines, but in this
particular case, I don't think it would be a very good
idea...

Alan, your findings on the computer are running true to what
I have seen over the years of using horizontal loops. However,
your computer program is great for the desktop but when you
are putting up the 'real' antenna, you will notice that using
three supports vs 4 supports will give your antenna wire a
bit more stress because of the longer runs and fewer
supports.

Also, if you change the feed from a corner of a 4 sided horiz.
loop and move it away from a corner (using an 80 mtr loop)
about 20 feet, I think you will find that the adjusted feed point
will begin to change the 4 sided loop performance to more
like the delta horiz. loop. You normally would Not want to
feed the 80 horiz. loop, 4 sided, in the middle of a side. The
Zo is a major change from feeding at or near a corner.

You should just put up a horiz. loop and start keeping a
good set of data notes. As you are learning more about
them, I will bet that you will soon find that some computer
programs and even lots of textbooks are not up to
date with the horiz. loops actual performance.EZNEC
seems to have a good loop program. But its not gospel!

Source record: 138357

Hi Bill
Unlike some "helpful" answers your getting, I'm going to try and answer your question. To the best of my information, conventional coil and cap traps can have a higher Q than coax traps. However, I think that either one will work. I think that the conventional traps are easier to build and with the better Q makes them the best chouse. By the way a good capacitor for the conventional traps would be a length of coax. RG-8 has about 30pf per foot capacitance and is rated for 3800V. At a 1500w output there could be 1900V or more across the trap capacitor.
Anyway either type of trap should have all the Q needed to work.

If I can be of any help let me know.

Walter
Thanks for the valuable feedback. I do subscribe th the position you noted of using computer generated info basically as a ballpark estimator. I found that to be especially true with trying to optimize an INVERTED-L and that impedances were ballpark but actual physical testing TWEEKED THE DESIGN. I had two thoughts in mind when I started dabbling here with EZNEC. First was to look at what to expect for a field friendly 80m SQUARE LOOP and then in my QTH situation, the house and 2 trees made for a nice DELTA arrangement.

The recent article in QST confirmed my crude results for the SQUARE LOOP as did the data presented by K0EZ and his 80m loop. THAT deep null overhead was of concern in that for 80m the NVIS was the primary consideration for enhanced local communications. Seeing the disappearance of the null on the DELTA seemed to provide an acceptable set of lobe patterns and impedances.

I will get the opportunity over the summer/fall to try both with great anticipation of how the actual measured results and performances compare

Thanks again--Alan KB7MBI

Doc, WW5LZ wrote:
"The point of not using a connductive mast is that you decrease the number of contact points between mast and structure."

When lightning strikes your elevated antenna atop your non-conductive mast, the lightning comes into your shack via the metallic feedline unless you take diversionary measures.

Let`s consider medium frequency stations. All as far as I know use conductive vertical antennas. Those that I worked at never had lightning in the shack including inside the radio. Though directly struck by nearly every storm in the area, the closest the lightning ever came was the coax. It rarely got to the coax. Usually it flashed at the Faraday screen between the coils coupling the antenna.

Best regards, Richard Harrison, KB5WZI

Hello Bill - been some time!

Coax-cable traps will work fine. Their main advantage is that they are made from cheap and commonly-available materials. Their disadvantages are:

- somewhat lower Q than conventional traps of the same size
- more difficult to adjust to exact frequency
- require prototyping (tolerances of coax and PVC pipe are such that you can't just wind 'em by formula and assume they are on frequency)
- LC ratio is not adjustable, and tends to be higher L/lower C than usually seen in LC traps
- coax traps are asymmetrical (don't turn them around!)
- have to be careful not to violate minimum bend radius of coax.

I have found that RG-58 with solid dielectric and stranded center conductor is about the best stuff to use.

Good luck!

Alan,
I'm confused. What 'deep null' overhead are you
talking about? Modeling either the 'delta' or 'quad'
loop at any height close to 30 feet doesn't yield a
'null' overhead. In fact, that's where the major
lobe is. What am I missing?

>(Netherlands).

I keep hearing about these swl "magnetic long wire baluns" but I'm not sure why you need one, and whether it is really helping things. On the back of your 535 (I assume it's the JRC receiver) there is both a 50-ohm coax connector and a hi-z random wire connector. If you have a long wire, I'd just connect it directly to the hi-z connector.

Put up the longest, highest piece of wire, of any length, the longer the better. That is your "best antenna."

Don't waste your money on the T2FD. If you have money to burn, go have a big, juicy steak dinner :-)

Have fun...

> free lunch...

Ain't it th' truth! I often get at friendly odds with my colleagues in a "certain" SAR
organization who desparately want to find a "beautiful", easy, and spouse-friendly
kind of mobile HF antenna. But then they wonder how come their mobile doesn't
quite make it into the state-wide HF net, or why people keep asking for relays on
the "weak" mobile, and OTH, why *some* mobile stations never seem to have trouble getting to the NCS. To purposely oversimplify, it takes a BIG, UGLY antenna to get a BIG BAD signal out! If you want "Pretty", you can get it; if you
want "PERFORMANCE", you can get that, but the 2 concepts will not mix.

My philosophy is that, because lives can be in the balance, and messages MUST
get thru, I don't have time to do the repeat-repeat-repeat thing. So I am willing to endure the giggles, the ridiculing smiles of people as I drive past with the big
3" Carolina Cyclone II on the bumper. When not engaged in SAR activities, it
is satisfying to be able, most of the time, talk to whomever I can hear--I don't try
to compete with the BIG contesters, however. But I get quite a few compliments
on my mobile. I ain't the biggest signal around, but I hold my own--and I thank
Amateur Radio for continuing to teach me how to apply what I learn from my hobby to that of lifesaving and home security--while having a ball in the process!

As to the so-called "tuners", couplers, hamsticks (dummy-loads-on-a-stick), they
stink on the low bands, and there truly ain't no free lunch!

Having just got the tower up and the beam mounted, the next step is to side-mount my duo-band and A-99 verticals. It would be a lot easier to mount the sidearm with the antennas premounted. It would also be a whole lot easier to mount the sidearm upside down, thus having inverted verticals. What would be the overall disaster in doing this?

"Put up the longest, highest piece of wire, of any length, the longer the better". That is the standard advice. Problem is, that usually it is a long way from satisfactory. It works very well if your receiver is located in a very electrically quite spot but that is seldom the case. Usually, there are computer monitors, TVs, electric appliances, ect, putting out enough EMI to make such an arrangement less than satisfactory. Shutting down everything in the house that could cause a problem is not very practical. The solution is to run coax to the random wire that is located as far as possible away from these noise sources. The "magnetic long wire baluns" that you here of aren't baluns at all. They are 9:1 impedance transformers. Connecting a high Z random wire to coax does not work to well. The loses are substantial. The transformer helps substantially. It, of course, does not provide a prefect match but the average impedance is lowered enough to make signal transfer much better. The commercial "magnetic long wire baluns" are a bit expensive at about $60.00. Most people make their own.

I think they are assymetrical only to the extent that the length of the trap is added to the wire on one side and subtracted from the length of wire on the other side. Subject to the foregoing they are usable in either direction. In any case the length of the trap at lower frequs is insignificant. Are these your findings ?

Many antenna designs are DC grounded. They are also effectively at ground for low frequencies - which is where most of the power in a lightning strike is located.

I have seen repeater systems that have had direct strikes to the antennas - while the stations were active. The only damage was to the antennas - and in most cases the antennas only had a hole melted in them. This is necessary in many parts of the country that may have lightning storms just about every day during the summer and fall.

These are transistor based repeaters, which are more susceptable to high voltages than the old tube stations.

Also at the top. This minimizes the voltage differential between the
coax and the tower. If the tower is tall, it may be desirable to ground
the shield at multiple places.

Yep. I never used gas tubes except on old tube based systems. In
retrospect, they were probably unnecessary even then.

Thanks for the help, fellas...

I'm thinking more along the lines of how to implement an isolated RF ground on the truck, rather than spending 20 years going through a truck I'm only going to own for three...

I only run the inverter when I'm parked, so I can charge the phone, but the fridge has to stay powered on most of the time.

The bands of interest are 20 and 40, with a possibility of 75 as well, but I'm not so worried about 75 right off...

I'm planning on installing my 706MkIIG and LDG AT-11MP in the truck for the rig, so I'll be able to "tune around" most any impedance mismatches...

Thanks again...

Source record: 138233

I am not radiating much of a ground wave on 80M and 160M. Testing
with an RX only 1/2 mile away (line of sight) I see only 1/10 the
signal I see at 10M, 20M and 40M. My tuner gets SWR down to 1.0 on
all bands. I hear a lot, but no one seems to copy me.

I just finished installing what I think is the highest, most antenna
that I could install on my property: An Alpha-Delta DX-LB+
multi-band inverted V dipole. It has separate dipoles for 10M and 20M
and they work fine. It has a shortened dipole for 40-80-160 with four
loading coils. See:
http://www.alphadeltacom.com/pg1.htm

Its center is 40 ft up. Its ends are 12 ft up from the ground. The
terrain has a substantial slope along the antenna -- dropping roughly
15 ft from end to end. Therefore, one end is 15 ft. higher than the
other end (as measured from sea level)

What is happening?
-Is most of the signal going straight up?
-Will it help to get the ends higher?
-Should the ends be at the same height above seal level -- or the
ground underneath each respective end?
-Is this kind of shortened dipole simply very weak at the low
frequencies and requires an amp?
-Is the summer season a factor in ground wave strength?
-Is there anything else I can do?

Is there such a thing as a white color Ham Stick? Believe it or not I need a white one. Had thought about painting a black one but it will be in a harsh enviornment and I am concerned the paint will peel. I know there are several manufacturers of this type antenna. Maybe one is white?

Thanks

No reason you couldn't put white shrinkwrap over the manufacturer's
black shrinkwrap. A hair dryer can shrink it. I don't think paint
would stick.

If the vertical is VHF or UHF (built-on ground plane) side mounting is fine. Get it as far as you can from the tower so the tower won't de-tune it. (And don't worry about which sideband to use!! ;-) The absolute best place for it would be above your beam. The higher, the better.

Hi, Jerry...

I almost bought one of your Tarheel antennas. It looked to me like one of the two best I could find on the net, but I never had seen one in the flesh. I wanted something other than those "mobile RF chokes" most screwdrivers look like. Unfortunately, when I called, nobody was there to answer.

If I may insert a small plug for a competitor with whom I have absolutely no connection except as a user, there IS one screwdriver that's very nice looking and even XYL friendly... the Stealth II, a patented design from Hi-Q Antennas, and the one I was able to make contact with. The coil is about 10" long and all tuning is internal. The length of the antenna never changes and the coil is sealed against dirt and moisture. I have the four-inch diameter model. Excellent performer... a few db (less than an S-unit) better than the 3" model I originally bought. But be prepared to spend some serious bux!! You're absolutely right... there ain't no free lunch.

Lowe's and Home Depot carry an aerosol paint that is designed to adhere to vinyl- so well that even flexible seat covers hold up for years. Although polyolefin is not a pure vinyl- my guess is that this will work very well.

>direction. In any case the length of the trap at lower frequs is
>insignificant. Are these your findings ?
>---
Reg,

My findings are based on 80-40 dipoles using traps made from RG-58 and PVC pipe. Traps were tuned to 7050 kHz on the bench (no wires connected) with a GDO, and antenna lengths adjusted for minimum SWR at 7050 and 3575 using an SWR bridge. I've built several of these since 1984, and all have behaved the same way.

What I've found is that turning the traps around makes a marked difference in the wire lengths needed for minimum SWR. The difference is much more than the trap length. Rather than deal with constant confusion, I simply standardised on "center conductor of coax in the trap goes towards the center of the antenna", and had no more problems.

Main point is to know that the effect exists, and is easily avoided.

> -Is most of the signal going straight up?

Yes. As most hams are on 160, you're basically in NVIS mode due to lack of antenna height. A 1/4 wavelength on 160 is around 250 feet. You and nearly all the rest of us aren't even close. But they DO work out ok. See below.

>
> -Will it help to get the ends higher?

No.

> -Should the ends be at the same height above seal level -- or the
> ground underneath each respective end?

That's of little or no consequence.

>
> -Is this kind of shortened dipole simply very weak at the low
> frequencies and requires an amp?

Shortened dipoles are always "weaker" and of narrower bandwidth. An amp can help your transmitted signal be heard better, farther.

>
> -Is the summer season a factor in ground wave strength?

Nope. Summertime noise on 160 is always a factor, though. It's often at a too high a level for good reception even when all stations involved are using optimum antennas.

>
> -Is there anything else I can do?
>

Probably nothing practical. 160 is far better in the winter months. Most don't do a lot of work there during the spring and summer "thunderstorm" months. Far too much static. Try it on a very cold winter night and you'll hear things you never even suspected were on the air during summer.
You'll work 'em, too. On CW at least. SSB and AM are done too, just not as easily.

Few years ago I wanted to put up a temporary antenna for 160. With winter close on my heels, I bought and hung a Alpha-Delta DX-A Sloper at 30 feet on the tower. It worked so well I left it up even after I got a fullsized dipole hung the next spring. It's still up for use as a backup.
Those things seem to work far better than they have any right or reason to. Maybe it loaded the tower as the "other half". :-)

Source record: 138242

Alan,
Okay, found my problem. I was only checking on the
primary frequency. When going higher than the primary,
there is a 'null' that developes with a corresponding
lower 'take-off' angle, for the 'delta' loop. Not so
for the 'quad' loop (no null).
Some days are better than others, and the other day
was one of my 'slow' ones. I always get to where I'm
going, but seldom in a straight line. (And any other
excuses that may apply)

Message-ID: <3D397E30.CB6ACA40@icok.net>
Source record: 138243

Ben,
Depends on how you define 'okay'. The antenna is
too large for the tower at whatever the wind speed the
tower's rating is for. There is a 'fudge factor' built
into the tower's ratings, but it is NOT a good idea to
rely on that. Almost all hams overload their towers.
It isn't a good idea at all, but most seem to get away
with it (at least for a while). Best advice is to buy
lots of insurance...

Doc
There does seem to be a lot of varying opinions regarding high angle null. In discussing say the quietness of the loop antennas one may wonder if the it is the deep high angle null cutting out high angle noise or the fact the loop static is naturally bled off by design (or both). The null predicted is very sharp and very high angle where most signals are not--even close in ones (should be maybe 80-85 degree vs 90 degree).

If one looks at an INVERTED-L it is a bit noisier than many and maybe because it does have no nulls.

This is all very fascinating stuff. As pointed out by Evan K9SQG the real proof is in the performance. I sort of think that the analytical gets you in the ballpark and the real world testing addresses the unknowns in the calculations. In the question of the loop being a bit quieter antenna, maybe, just maybe a high angle null exists, but then it may just has to do with the non-static build up.

When looking at CEBIK's lobes for the Inverted-L he shows two distinct lobes--one for the horizontal wire and one for the vertical wire. In reallity it is probably a marriage of the two lobes. With the loops we may not be getting the complete picture either depending upon how we model

Thanks for the feedback.

1452. Help with Butternut HF5B please!

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-20 17:35:49 UTC
From: MW0CDO <gw7lhi@hotmail.com>
Message-ID: <ahc718$rdo3n$1@ID-117699.news.dfncis.de>
Source record: 138245

Hi there.

I have an original Butternut HF5B "Butterfly" beam.

The problem is that it arrived without assembly instructions.

So I downloaded 3 different manuals from Benchers' site, which are very useful but they do not quite match up with the antenna I have!

Some of the capacitors have been substituted by Butternut / Bencher for whatever reasons over the production life of the antenna. Original versions had 2 ceramic capacitors.. one on the driven element and one on the reflector, the rest being tubular metal ones.

I believe that I have the original version, where the 10/15/20m capacitor on the driven element is a ceramic type rather than a tubular metal one. (Part ID is EE in the manual)
The measurements given in all the manuals I have state that this capacitor should be initially connected to the radiator 45.5 inches from the driven end.. but this is physically impossible given the parts I have here! I have no reason to suspect that any of the supplied parts are incorrect, even though the antenna was "previously enjoyed"
There is also a ceramic capacitor on the reflector, and the dimensions given for it's placement are easily achievable.

Can anyone tell me the approximate distance from the driven end of the element that this capacitor should be connected at?

I would be very grateful if anyone could send a scan via email of the driven and reflector suggested starting dimensions and tuning procedure from the original Butternut manual to ptomlinson@ntlworld.com
Or tell me where I could see a reasonable picture of an original HF5B on the 'net?

Many thanks in advance!

Paul MW0CDO in sunny South Wales UK.

1453. Broadband Folded Dipoles & Delta Loops

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-20 19:32:28 UTC
From: K7HMP / 4 <k7hmp@arrl.net>
Message-ID: <3D39BACC.ED041C81@arrl.net>
Source record: 138246

I've recently become interested in a couple antennas I've noticed over the years in catalogs and magazines. They appear to be "normal" Folded Dipoles or Delta Loops; except, they are fed with a balun and have a "termination device" (read "dummy load"?) at the midpoint. The most common one is the B&W Broadband Folded Dipole which will apparently work from 1.8 to 30 MHz with an SWR of less than 2:1.

Has anyone used these with any success? Is the 2:1 real? Or, does the "termination device" do something with other portions of the power, so that although it isn't being reflected, it isn't radiating either?

While I know that termination resistors are a time-honored technique for Rhombics - which work great on a broad range of frequencies - I'm less sure I understand why they would work in a dipole type configuration.

Are their any sites or books that have a layman's explanation of how or why these antennas work?

Appreciate the insight either direct or posted here.

Doc, W5LZ wrote:
"Then instead of worrying about grounding, you`re saying he should use a Faraday shield?"

That would be also use a Faraday shield along with an excellent grounding system.

I don`t see many hams using Faraday screens (shields).

Nearly all broadcast stations use Faraday screens. The stated purpose is usually for harmonic suppression as the screen eliminates capacitive coupling to the antenna. Fact is the screens are extremely effective lightning stoppers. The screen is directly grounded. The screen is usually heavily pock marked from all the lightning hits it has taken. The arc-gaps across the base insulators are usually pristine with no marks on their painted surfaces.

Station coax is usually buried. No lightning is going to ride its surface into the shack. But, many stations have above ground routing and the coac is grounded at least at each end of a run and often at many other places too. The skeletal type is grounded at every supporting pole.

The station has excellent grounding via the radials at every tower and an elaborate grounding system at the shack. Lightning doesn`t get far inside the coax which rejects the common-mode at radio frequencies. For low frequencies there is direct grounding in many circuits in the station and at the towers. The center-conductor of the coax is often d-c isolated so that an arc in the coax can be used to d-c trigger a momentary carrier interruption to kill the arc.

Best regards, Richard Harrison, KB5WZI

Bill Nelson wrote:
"Also at the top (of the tower, ground the tower-mounted coax shield).
This minimizes the voltage differential between the coax and tower."

Yes. That is an important point. It is best to shift as much energy from the coax exterior to the tower as possible. Nearly all our antennas used folded driven elements and these were securely connected with the tower at the mounting point.

Suppliers often urged us to try an ungrounded antenna type. We did relent at times and nearly every time the antenna would soon be severely damaged or destroyed by lightning unless we protected it with a 1/4-wave short-circuited stub. The coax was grounded at the top in all cases.

Best regards, Richard Harrison, KB5WZI

Its being radiated all right, only as 'heat' from the dummy load, i.e. resistor at the feedpoint! Works good, but so does a regular dummy load...Flattens the swr right out! Which of course is the whole point of the resistor.....Some rf gets out, but a lot of it is heating the resistor...bummer.....

Here are some sites you may want to review. Note there has been a lot of discussion on the T2FD and B&W folded dipole over the past few years. Being broadbanded note it will not be as efficient as antennas such as dipoles cut for specific bands. Although not the most efficient it does offer certain conveniences such as not tuner necessary but at a price of loss of power. On 160m the B&W will be as much as 16dBlower than a resonant dipole at same height acording to reports but approach efficiencies more acceptable at the upper bands.

"Are there any sites or books that have a layman`s explanation of how or why these antennas work?"

L.B. Cebik, W4RNL has modeled these antennas and presents their performance on his web pages.

Just search using L.B. Cebik as your keyword. W4RNL will likely work as a key also. Cebik`s exercise is likely to be believed.

Best regards, Richard Harrison, KB5WZI

Dave,
I think your talking about antennas like B&K's folded
dipole. If so, then yes, they do work. The problem is
that they work very badly. Can't say exactly why, but
I do know from experience that they are absolutely NOT
worth having, unless you can't have ANY other kind of
antenna.

Here we go again. Now someone will speak up and tell us how they worked VK with one and just loves it. Well I bought one a few years ago just to see how bad the B&W really was. It was BAD BAD BAD. Very heavy, very ugly and very dead. Oh sure, signals could be heard and some stations worked. But they were down at least 20-30db on 80 meters! Higher bands were a bit better...if you call it better. The only thing going for it is low swr. Only the government would buy one of these things. 73

It is necessary to distinguish between performance in reception and transmission.

In transmission, the resistor is a loss. Signals at the other end will be low.

In reception, the resistor is also a loss, reducing both the desired signal and the accompaning noise by the same amount. If the noise is still lower than the noise floor of the receiver system, the S/N is still the same. The loss can be compensated by turning up the RF gain, which is usually done automaticaly.

Although lossy, the system can be useful.

Thanks Jim. I was wondering which way they were supposed to go!

Just built trap #1 usiing measurements from 1981 QST article by W3JIP.
GDO is broken, so I coupled the sig generator to the trap and watched
the voltage across it with an RF probe. Big peak, but around 17.8
Mhz. Spread the turns out a little bit and then checked again. Now
it shows resonance at around 18.12 . Just where I want it. This was
easy.

1469. Impedance Question

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-20 23:12:13 UTC
From: Robert Rose <rgsrose@tiac.net>
Message-ID: <ahcqsu$i3l$1@slb1.atl.mindspring.net>
Source record: 138262

Hi,

Am new at this, so the following, please:

I'm using a simple long wire antenna for listening only (<30 MHz)

Goes directly to my high-Z receiver input, and works fine.

If I add an inline lightning arrester, which is of the coax type, I guess I would
jury rig it with a bannana plug.

But was wondering since these protectors are 50 ohm Z, am I creating such a mismatch that it would not be a good idea? (the long wire, I'm told, is probably around 600 ohms)

To use the lightning protector, would I "have" to go to a coax feed line to the long wire in my attic,
and use a balun, even though the protector itself is only an inch or so in length?

thanks,
Bob

Never had water get in conduit yet.
This has only been in a few year, but no problem so far.
I had one run made of 5" sewer pipe I used for 17 years. That used a capped
off 45 with drain holes in the bottom, but never needed them.

I seal every joint in the PVC. You'd have to cut it apart.

You can jury rig it with a banana plug. Many of those devices are only
a spark gap anyway.
As far as the impedance mismatch, your random-wire system is of a
different impedance at every frequency...may be 30 ohms at one and 3000
at another. You shouldn't notice any difference with the gadget inline.

I don't mean to nit pick but......
You won't notice any difference because the device is small compared to the wavelengths in question.
(frequencies <30 MHz => wavelengths >300 feet)
All these 2-inch-long "arrestors" do is allow static buildup to leak off before it goes through your radio.
A direct strike is likely to smoke your radio anyway.
Why not just disconnect the antenna when not in use?

1474. Re: Horizontal DELTA and SQUARE loops (EZNEC DEMO) question

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-21 01:10:16 UTC
From: N4LQ <N4LQ@igLou.com>
Message-ID: <3d38b857_3@news.iglou.com>
Source record: 138364

Currently I have both an 80m square horizontal loop and a 40m delta
horizontal loop installed at nearly the same height. I've tried moving the
feeder around on the 80m loop and it does in fact change the nulls slightly.
I have a huge null to the west and all the 6's are weak. Moving the feeder
to near the center of one side was supposed to move the null. It did help
but 6's are still weak.
This is what prompted me to try the 40m horiz delta. When I first put it up,
I was totally astounded at the huge difference. The delta has no obvious
nulls. 6's are now 30db stronger than the 80m loop (on 20m).
I like to use these antennas for all bands but for 40 -10m, the delta is
better, much better, in all directions. All signals on 40m, dx and local,
are unbelievably stronger.
The 80m loop is coming down. I'll put something else up for 160 and 80m.
Maybe my old inverted L.
This is the kind of stuff you never find out unless you can have both
antennas up at the same time and do a lot of A/B testing.

Doc wrote:
"Bob,
That`s an artificial distinction,---"

Bob had written: "It is necessary to distinguish between performance in reception and transmission."

The distinction is significant.

At a tranciever the local noise may almost obliterate reception but be inaudible on the transmitted signal from the transciever. Noise is usually a reception problem, not a transmission problem.

Seldom is antenna loss a factor in reception for a good HF receiver. Just turn up the gain to compensate for antenna loss as Bob said.

Most of the commercial HF receiving stations in the world use antennas which employ loss. Rhombics have dissipation resistors for unidirectional termination. Beverages hug the earth which extracts a high energy toll.

But the commercial receiving station antennas are highly directional and thus shun interference. The gain is turned up to compensate antenna loss but since interference was ignored in many directions, the S/N of these antennas is better than high efficiency may have provided in a less directional antenna.

My experience includes a commercial HF receiving station with a large antenna farm full of those rhombic antennas (for space diversity, three in each direction) with their lossy termination resistances. The receiving station associated with those rhombics was filled with Crosby and Pioneer triple diversity receiving sets. They worked around the clock providing high quality program relay for broadcasts.

At home I used a Beverage antenna with frequency diversity which worked like gang busters to receive WCBS and WWL in Europe.

Best regards, Richard Harrison, KB5WZI

Bob,
With the antenna being in your attic, I wouldn't
bother with the lightning arrester to start with. If
your antenna takes a lightning strike in your attic,
the radios are going to be the last, and least of your
worries...
'Doc

PS - And yes, the difference in impedance will make
some change to the antenna's input impedance,
but nothing noticable.

I assumed he must be referring to one of the harmonic bands although he
didn't say so. Obviously on the fundamental, the loop at 30ft has just the
opposite of a null! My 80m loop on 40m had such a narrow vertical pattern
that only a few signals were strong while the 40m loops performance is
outstanding at what seems like all angles (on 40m of course).

> worries...

The name 'lightning arrestor' is an example of overly-ambitious nomenclaturism. Such bad naming can lead to muddled thinking about the capabilities and purpose of such devices. Can such a device "arrest lightning" ? Obviously not - except perhaps as a small part of a much larger lightning protection system. The device in question is more accurately described as a 'static discharger'. 'Static' (sic) in this case could include coupled EM from *nearby lightning strikes*.

My house in NS has never been (directly) struck by lightning. The location of the main strike was obvious by (for example) the exploded pine tree and was several hundreds of feet away. But I've had hundreds dollars of damage to alarms systems, telephone equipment, battery chargers, and so forth caused by these nearby strikes. The common element has always been *long runs of wiring INSIDE* my RF transparent house.

'Doc is correct that direct strikes are an important issue, but coupled EM induced damage to electronics is far more common than direct strike damage. It isn't a good idea to concentrate only on direct strikes and to neglect the coupled EM from nearby strikes.

It is a mistake to ignore any long runs of *indoor* wiring (whether labelled by man as an 'attic antenna' or 'telephone wiring' or 'intercom' or whatever....as if the name mattered to the gods of EM). Most houses are completely transparent to coupled EM (as from nearby lightning strikes). This concept has not yet sunk into the collective ham radio mind.

NQ5H had some good advice - "Why not just disconnect the antenna when not in use?"

Got a few questions about the design of this antenna.

1. Why use brass instead of copper? Copper is a better conductor,
and readily available.

2. I understands the reasoning for the lengths of tubing & rod, but
what about the diameter? Were these just convenient values, or was
there some math behind the decision?

3. What happened to the original site? Does it only exist in
google's cache now?

>On the topic of burying coax, how deep/far should coax be buried to offer
>some lightning protection?

Lightning takes the path (paths) of least resistance to ground. If you have
a beam on a well grounded 50' tower, most of the current will go to ground thru
the tower. However some of the current will try to flow thru your coax and rig
to ground. Burying the coax would not shunt the current to ground, except for
some capacitive coupling. A loop or two in the coax might help, as it would
act as an rf choke.
Another example, you have a dipole that is the highest structure in the area.
It takes a direct hit. The only path to ground is thru your coax and rig.
Burying the coax again provides only capacitive grounding. How deep? 2-6
inches. How much will this help? I don't know because Lightning is difficult
to summon for experiments.
The best way is to insure lightning has a path to ground that is not thru
your equipment. Or try to get your antennas less attractive to lightning.

Pure copper is too expensive, and has not enough mechanical strength, i.e.
impractical.

>
> 2. I understands the reasoning for the lengths of tubing & rod, but

tube diameter influences antenna BANDWIDTH, i.e. what is the frequency range
around the center frequency that the antenna responds to (aka 3db
bandwdith). The wider the tubes, the wider the bandwidth, but wider
bandwidth makes a less effecient (smaller gain) antenna. There's a price for
anything.

Yes, on the low bands.
> -Will it help to get the ends higher?

Some.

> -Should the ends be at the same height above seal level -- or the
> ground underneath each respective end?

Not really critical. The higher the better, but if one is lower than
another, no big deal.

> -Is this kind of shortened dipole simply very weak at the low
> frequencies and requires an amp?

It must not be the most efficient antenna on the low bands. Someone
should at least hear you. I talk on 80m all the time with only 100w,
and I don't have any trouble using a normal full size dipole. And the
band is noisy here also.

> -Is the summer season a factor in ground wave strength?

No, but there is a lot more noise to cover up any weak signal. Also,
bear in mind, the ground wave from a mostly horizontal inv vee is not
going to be very good. Any good vertical would eat it up in that
regard. Why is ground wave so important? Regular people you talk to

that are close? Most of what you would work on 160 and 80m will be skywave. And yes, with your antenna at it's fairly low height, it's shooting straight up. You should do fairly well to regional stuff within a few 100 miles. If not, something is not up to par. You could easily model your antenna just to see the pattern on each band. It varies quite a bit when the antenna is over a wavelength high on 10m, and about 1/12 wave or so high on 160m.

> -Is there anything else I can do?

Depends where you are trying to work. For ground wave or dx on 160m, a vertical would be better. But it will need radials also...A full size dipole is better than a loaded dipole. You might consider a "Z" dipole. It's nearly as good as a regular straight dipole. No loading coil losses at least...But if you can't squeeze it in, you can always fire an amp up I guess. MK

1487. Better 2M vertical?

J. Harvey,
While I agree with you about the terminology
I still think a 'lightning arrester' isn't needed
for an antenna in an attic. Much of the 'static'
discharge you have with an outdoor antenna is
simply not present on an indoor antenna because
it isn't exposed to weather.
From what you said about your own experiences,
either you didn't use a 'lightning arrester', or
it was ineffective. Even so, I seriously doubt if
one would have helped to any great extent. There's
nothing wrong with trying to be safe. But there's
not much point in putting a 'back-up' alarm on a
statue either...

==========

The effect of diameter on bandwidth is less than is popularly supposed. It's all hearsay. No-one ever gives any figures of what they are talking about.

Programs DIPCAGE1 and SWR_FREQ provide numercal values of bandwidth versus element dimensions which apply to simple types of antenna. Run programs on a 'what-if ' basis.

Download in a few seconds, not zipped up, run immediately.

>Thanks Jim. I was wondering which way they were supposed to go!

Bill and group,

I don't think performance is really affected by which way they go, as long as both sides of a dipole are done the same and the antenna is trimmed to frequency. Where I got into mass confusion was when I "copied" an existing antenna without regard for trap orientation.
>
>Just built trap #1 usiing measurements from 1981 QST article by W3JIP.

That's a lower-Z trap design. See QST for December, 1984. N4UU's article is the one I've used.

>GDO is broken, so I coupled the sig generator to the trap and watched

Yes, but pairs such as telephone, Romex power, or intercom pick up little induced energy between the wires. Induced voltage may be high, but it`s the same on both wires of the pair. Peril to the connected load is usually small until two systems come together in the same box. These systems may have vastly different potentials.

Modems and answering machines are at risk because they are connected both to power and phone lines, for example.

> On the topic of burying coax, how deep/far should
> coax be buried to offer some lightning protection?

I had an 80-m dipole strung up fairly low between two trees. The RG8-type coaxial cable was run along the ground (not buried) for about 200 feet. When a massive lightning bolt hit a tree several hundred feet away on the corner of the property, there were roughly foot-long sparks jumping from the disconnected end of the coax under the desk. I was surprised that foot-long sparks would decide to come all the way into the house after 200 feet of coaxial cable laying on the ground. I guess the ground conductivty of my property leaves something to be desired...

Leonid, sorry to disagree. Bandwidth of an antenna has no effect on
radiating efficiency. Why should it?

In fact, as tubes are made wider, efficiency will slightly increase because
of lower RF loss resistance.

> for example.

My lightning theory includes another possible damage mechanism not included in your explanation: 'self capacitance'.

If a device has an element with a significant self capacitance that is not directly connected (or at the very least, properly bypassed) to the long wiring, then the lightning may cause internal damage as it attempts to bring the entire device up to the high common voltage and the part with the significant self capacitance lags behind. Any device that has an ungrounded chassis (very common these days) is at risk. This problem is more common with new school design than old school design (old school designs with 3-prong plugs and a 'simply grounded' metal chassis are less of a problem). You have to imagine trying to quickly bring the chassis up to the common voltage *through the long signal or power leads*.

Real World Example - My battery charger system was floating at the end of its power connection and (in theory) the whole package should have happily floated to a new common lightning-induced voltage. The problem was that the battery string (one car battery and six big Gates batteries) presented a fairly large self-capacitance that had to be pulse charged through some sensitive part of the battery charger circuit. The damage in the battery charger was not in the primary side, but in the secondary side close to the battery string. The battery string had to be pulsed up (and down) through the pass transistor. The voltage difference across the pass transistor as it *tried to do so* was too much and it shorted out. The battery charger worked 'just fine', it just didn't stop and it boiled the batteries dry. They whole string was at about 20 volts pulsating DC by the time I noticed.

If I had grounded the negative side of the battery string to the household ground (assuming that the battery charger didn't mind such a connection), then I'll bet that the low impedance connection would have been able to pulse the battery string up to the common mode voltage without damaging the battery charger.

The concept that floating systems at the end of a single cable are immune from lightning induced damage is overly simplistic. Self capacitance needs to be included in the theory. Devices installed at the end of a single long cable run *can still be damaged* if they have significant self capacitance connected by a 'damage susceptible' link to the long wiring. If the device's self capacitance needs to be 'charged up' (and down) through a semiconductor (for example), then it is susceptible to damage. The more susceptible the 'charging' path, the less the self capacitance required to result in damage.

This 'self capacitance' mechanism is not mentioned in the text books (so far as I've seen). They always trumpet the line that floating devices are relatively immune without any mention of self capacitance.

This is another concept that has yet to 'sink in' to the collective ham radio 'uni-mind'.

I'm assuming that if the coax cable had been resting on the surface of a
salt-water bog for 200 feet (as opposed to dry ground), then perhaps the
foot-long sparks under my desk might have been just a little bit shorter.
It is an assumption....but I believe it is an obviously correct assumption.

I don't intend to use the ground wave on any of my HF bands. Since I couldn't raise anyone on 80 and 160, the ground wave test was all I could readily try -- as some kind of measure of signal strength

As to the vertical, the only practical one for me would be one of those screwdrivers on a tripod at ground level atop a medium-size (10 ft X 10 ft) copper or stainless screen on the earth as the ground plane. Would something like that be better for DX at 80 and 160 than a 40 ft high loaded dipole?

To respond to the question, about any depth that you're not going to disturb
later is fine. I once buried 2000 feet of 7/8 inch Andrews in something like
500 foot lengths about 18 inches using a rented ditch witch. 10 years later,
when I sold the super station to a non-ham, I TRIED to retrieve it. No way.
Tree roots had grown over it and it would separate rather than pull up.
Abandoned most of it in place and it was still perfectly good coax. Most
sections were still holding 9 PSI of dry Nitrogen.

Remember, some day, you might want to retrieve it.

From: Reg Edwards <g4fgq.regp@btinternet.com>
Message-ID: <ahejpr$e3r$1@paris.btinternet.com>
Source record: 138299

Jim, thanks for the interesting info.

Putting on my thinking cap, I think the electrical length of a trap changes because the overall diameter of the trap is much greater than either of the two antenna wires and therefore has a greater capacitance per unit length to the rest of the world. It behaves as a length of wire longer than its physical length. It could also be regarded as a lumped capacitance loading to the rest of the world.

When the outer conductor is connected to the 'unused' end of the antenna there is very little voltage between the outside of the trap and the rest of the world. Not very much current flows. The 'long' length of trap is connected to the unused part of the antenna so it doesn't matter very much how much more it is lengthened. The higher frequency inner dipole operates unaffected.

But if the outer coax conductor is connected to the higher frequency dipole, the trap lumped capacitance would detune it to a lower frequency and pruning would be required on the length of wire between the traps.

QED. ;o) I could perhaps include the effect in my COAXTRAP program.

Incidentally, I find an antenna-analyser type of instrument is easier-to-use and more accurate than the dipper type. It also gives an indication of Q.

Yes, the Q of coax traps is appreciably less than Q of the conventional type of the same physical size. This is because the inner coax conductor has a much smaller diameter than a solenoid wire. Not that this matters very much because it is the parallel resonant impedance of L / CR which really matters and C tends to be smaller with the coax type.

Doc, W5LZ wrote:
"Richard,
And you must have not paid attention to the topic of discussion."

Sometimes these postings are conversations and we respond to recent remarks.

Going back to the original question:
"To use the lightning protector, would I "have" to go to a coax feed line---?"

An attic antenna is less attractive to lightning than other higher surrounding conductors in most instances. In a penthouse this may be different.

Coax is a poor match for most end-fed wires. A step-up to the wire impedance is helpful in most cases.

Coax is a much better lightning protector for most radios than is the "lightning protector" proposed. Such protectors are usually superfluous. Induced energy will travel the coax exterior, the radio case, and the radio ground connection(s).

Without coax, an unbalanced feedline carries differential-mode surge energy and that can be bad for a radio. A gas tube may need 90 volts to fire and take a measurable fraction of a second to fire. That is not much protection for a solid-state radio.

Best regards, Richard Harrison, KB5WZI

Ken,
That's not easy to answer, there's a lot of variables
involved. In general though, I'd have to guess that the
dipole would be 'better'. I had an 80 meter antenna at
less than 40 feet that did pretty well. Not a lot of DX,
but almost anywhere in the US (KL's and KH's too).

1514. Cushcraft A3 Trap Question

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-21 17:14:01 UTC
From: "Christopher A. Bowne" <radiobwn@riconnect.com>
Message-ID: <ujlr10ak1aega9@corp.supernews.com>
Source record: 138307

I am currently using the driven element of an old Cushcraft A3 as a rotatable dipole. Up until recently, I have had low SWR on 20, 15 and 10 meters. Now, only 10 meters is giving a good match. I suspect that there may be a problem with one of the outer (15 meter traps). Assuming that I cannot correct the problem (such as cleaning out bugs, etc), is it possible to substitute one of the outer traps from either the reflector or director elements? Are all the element's traps for a given band resonant at the same frequency, or are the director traps resonated slightly higher in frequency, and the reflector traps slightly lower in frequency vs. the driven element traps?

Ken, KC2JDY wrote:
"What is happening?"

Ken`s loaded assymetrical inverted "V" has some horizontally polarized radiation which at 40, 80, and 160 meters is mostly high-angle due to the low 40-ft maximum elevation above earth.

The vertically polarized radiation comes from sloped sides. As a vertical radiator, the antenna height varies from 0.3-wavelength at 40 meters down to 0.076-wavelength at 160 meters.

Short verticals can produce usable radiation at fairly low angles, but require good earth around them for greatest satisfaction.

Source record: 138310

Anyone ever replaced the SO-239 connector on their 259? Mine is worn to the point that the center connector no longer has enough compression to make good contact with the PL-259 center connector. I tried bending the connector sections in to make for a tighter fit, but not had much luck.
Replacment of the SO-239 appears to be a major undertaking. It is soldered to the main circuit board as well as bolted to the chassis. Not impossible, but not easy either. Any useful tips or suggestions would be greatly appreciated.

>
not necessarily. the coax may have been picking up charge from the ground
along its length instead of bleeding it off to ground. in a lightning
strike the voltage gradient along the ground can be quite large. in high
current ground rod experiments that we did where i work it was quite
interesting to see the discharge across this surface of the ground when it
was wet, not exactly what we were trying to do but interesting anyway.
lightning can also 'burrow' underground creating mole like tunnels then
coming up quite a distance away, so just because the stroke didn't hit
something directly that in contact with the earth it can still receive
enough energy to cause problems.

1519. What Multi-Band Dipole to Buy for 1.5kW use??

I also had the need for an 80m-10m band dipole that works without a tuner
with the 50 ohm fixed tuned output on my SGC-500 amp. The results are on my
web page. You can use the same techniques to match a 90 ft long dipole except
for 80m where you will need an additional stub. But doesn't the AL-1500 have
a built-in adjustable matching network that can be used for tuning the
antenna system?

I built a j-pole and I love it. It is said not to have the gain of a colinear type and it probably doesn't. But, in a price vs. performance comparison, it wins hands down. I built one for 2 meters, cost for all new copper plumbing was <$7.00, a ten foot length of 1/2" copper pipe, 1 "tee" and 1 elbow fitting and two end caps. Plus 2 hose clamps for attaching the coax. If it is mounted at top of tower/pole the remaining ~3 feet of pipe can be used at the bottom of the tee as a mast.

I mounted mine on the tower side. Using scrap 1" PVC as standoffs, about 2 1/2 ' from tower.

Just make sure you water proof the coax end!

J. Harvey wrote:
"This "self capacitance" mechanism is not mentioned in the text books (so far as I have seen)."

Coils have self inductance produced by the current through them. Self inductance opposes change in the current in a coil.

There is need for another name to describe the effect coils can have on each other. This name is mutual inductance (M). There is a formula to describe total inductance of coupled coils:
Lt = L1 + L2 + or - 2M.
The + or - depends on coil phasing for the M. In other words whether the start of one coil is connected to the finish of the other coil, or the other possibility, that current flows in opposite directions through the coils.

Coils have self-induced voltage and so self-inductance is a useful term.

What is "self capacitance"?

Best regards, Richard Harrison, KB5WZI

hey jeepmon
you are leaving out comet there GP9 even though its a dualband antenna
has very good gain and is performing very well
the think that bothers me with the other two are they are made mostly of
fiberglass and that attracts lightening so i went with the comet which is
made mostly of ABS plastic
i think most vertical you get for 2 meters should be broadbanded enough to
cover the entire band and then some
also check out mosley and cushcraft they make verticals made from aluminum
good luck

Hi Steve -

W9INN has the best line of multband dipoles I have seen; and most,
if not all, will take the power. But he doesn't have a 7-bander like
you are looking for. It would take two of his: e.g., a 30/17/12 and an
80/40/20/15/10.

My setup uses an 80/40/17 and a 20/15/10. With this setup, there are a
grand total of only 4 traps; only 2 bands go through a trap (80 and 20);
and no band goes through more than one trap. (Note: These traps do
not use a discrete capacitor at all; he calls them "resonactors.")
I'm a believer... his stuff works great, and he's great to deal with.

My broadband vertical can handle 30 and 12 well, but those bands
don't interest me much.

1532. Re: Magloops

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-21 21:09:14 UTC
From: Reg Edwards <g4fgq.regp@btinternet.com>
Message-ID: <ahf7tpvg1@venus.btinternet.com>
Source record: 138174

Magloops come into their own domain when real estate and space is very short.

It is impossible for radiating efficiency to approach that of a 1/2-wave dipole until it consists of a 1/2-wave dipole bent into a circle.

Nevertheless, the magloop is the most efficient of all the small antennas which can be contained within a limited space. It is usable in the attic, on the balcony of an apartment, or in a small backyard where height is at a premium. It is best orientated in a vertical plane.

I say this from experience and theoretical mathematical analysis from fundamental principles. I have absolutely no connections with any antenna manufacturers, corrupt salesmen or authors of magazine articles.

If you are interested in any figures, download program MAGLOOP4 from website below.

Download MAGLOOP4 in a few seconds. Not zipped up. Run immediately. Use program on a "what-if " basis.

>to the rest of the world.

Sounds reasonable - it acts as a form of "capacity hat", end loading the
"inside" section at the trap frequency.

This effect is uniform for conventional LC traps.
>
>When the outer conductor is connected to the 'unused' end of the antenna

Exactly. So an antenna adjusted with the coax traps one way would be out of
tune with the traps reversed. The effect is minor, but enough to be worth
allowing for.
>
>QED. ;o) I could perhaps include the effect in my COAXTRAP program.

Agreed. Also, the dielectric properties of coax outer jackets may not be the best - they are not designed to be.

>Not that this matters very much
>because it is the parallel resonant impedance of L / CR which really
>matters and C tends to be smaller with the coax type.

End result is that the loading coil effect of the coax traps is greater.

"Richard Harrison"
> What is "self capacitance"?

Self capacitance can be quickly understood by the self-evident fact that it would obviously take a large amount of current to 'charge up' a very large (1km x 1km) plate floating alone in intersteller space (light-years from anything else). If you have difficulty imagining where the charge is coming from, then imagine another plate. Imagine a highly charged small plate meeting an uncharged large plate. Think about the resultant voltage on the two newly-joined plates as a ratio of the self capacitances.

Another example is when you suffer the pain of a static shock from touching a door knob - consider that the door knob is probably highly insulated on a dry wooden door (*not* grounded). The door knob's self capacitance will draw a spark as the voltages equalize. Presumably fat people suffer more painful sparks than thin people since they would have a larger self capacitance.

The often worshipped 'International Ground' is simply the self capacitance of the small blue planet Earth.

Hi Richard,

Self capacitance is the amount of capacitance seen from one point to
all points of the same surface - sort of a one terminal specification.
This may also go by the term free-space capacitance where the other
plate is at infinity. The standard value for an adult is 50 pF (to
give a sense of application and value range - application in this
sense of an adult is for ESD shielding and user coupling of hi risk
potentials and currents). The standard value of free-space
capacitance for a sphere (presuming its mating spherical plate has
infinite radius) is
111*r pF
(where r is the test sphere's radius in meters). This says nothing of
the close proximity of other conductors and insulators where the human
form in a natural environment typically presents 50 to 250 pF
capacitance (and inductance spec'd at less than 0.1ï¿½H, and resistance
in the range of 500 to 10000 Ohms).

Actually, Jeff is using self capacitance more in the sense of
distributed capacitance much in the manner of my last drawings of
Common Mode paths. His statement:
>The concept that floating systems at the end of a single cable are immune
>from lightning induced damage is overly simplistic. Self capacitance needs
>to be included in the theory. Devices installed at the end of a single long
>cable run *can still be damaged* if they have significant self capacitance
>connected by a 'damage susceptible' link to the long wiring.
is simply my observation some time back that seemingly benign Common
Mode effects may be imparted to a fully balanced system and still
present hazards. This snippet of Jeff's also illustrates the need for
the complete path's description - which, of course, includes ground
and coupling to it. His discussion presumes the surge impedance of
the Common Mode.

FYI - I just picked up another antenna bargain at
Radio Shack *Canada*.

Glass mount dual-band 2m/70cm Ham radio antenna.
2.6dB gain at 2m and 6.3dB gain at 70cm (YMMV).
50W handling capability.
Tunable for optimum performance.
Includes all cables, connectors, mounting and tuning hardware.

Cdn $ 19.99 + tax !!! (that's about US$14 FWIW)

Stock # 19-324

Link to picture and info...
www.radioshack.ca/estore/Product.aspx?product=1900324

Seems to still be available on-line and at some stores.

Dave, K7HMP/4, the original questioner wrote:
"Are there any sites or books that have a layman`s explanation of how or why these antennas work?"

I responded: "L.B. Cebik has modeled these antennas and presents their performance on his web pages."

Now, Doc, W5LZ asks: "Have you ever used a B&W folded dipole and made a comparison with an ordinary dipole for the band in use?"

As I said: A mathematical analysis beats testimonials."

That is true because customer satisfaction has as much to do with the customer as it has with to do with the product.

The math has no favorites when used properly. I think Doc is asking the wrong question, especially since I`ve neither condemned nor praised the Barker & Williamson terminated folded dipole. Had I made a comparison of the B&W item I would have shared the data.

I have erected many dipoles of several types on several continents and measured results. I have never used the B&W item. I would only consider using the B&W item where the transmitted frequency had to make large hops in a hurry and there was limited antenna space, or some other restriction that doesn`t come to mind immediately. I`ve seen testimonials and Cebik`s results and to me they seem to agree.
I don`t have to touch the stove to be satisfied that it is hot.

Doc also wrote: "Don`t do one of those slip and slide things."

Yes, and when did Doc quit beating his wife?

J. Harvey wrote:
"---it would obviously take a large amount of current to charge up a very large---."

Or, it could take a small current flowing for a long time. It really takes two surfaces to have a capacitance because there must be a charge differential. As I recall the formula is Q = CE. If the capacitance is small the charge (Q) can be small for a given voltage.

A large object in outer space may have a truly tiny capacitance to any other item due to enormous separation.

The lack of speed in charging a capacitance is as much a function of impedance in the charging path as it is the size of the capacitance.

I still don`t know why I need a self capacitance or the best way to get one.

Best regards, Richard Harrison, KB5WZI

Assume your allowable antenna load includes the rotator, mast, and
cables in addition to your antenna (unless the manufacturer specifies
a separate allowance for them). This means your tower could be
considerably above its design rating. Unless your wind speed is well
below the national average, it would be wise to keep the tower down
below its maximum height.

The ideal solution would be a heavier duty tower or a smaller antenna.
Lacking that, be conservative with the tower extension.

[On the existence of 'self capacitance'...]

"Richard Harrison"
> I still don`t know why I need a self capacitance
> or the best way to get one.

:-)

> Or, it could take a small current flowing for a long time.

I was presenting the *simplest possible* example (made of highly conductive metal). Don't complicate it until we achieve concensus on the simplest case. I thought that 'self capacitance' was a well established concept. (If I'm wrong, then I'm happy to learn.)

> A large object in outer space may have a truly tiny
> capacitance to any other item due to enormous separation.

Would the Earth make as good a 'ground' if it were only 1 cm in diameter ? I don't think so...

The Earth is quite far away from other objects (such as the Moon). Therefore it has a very small capacitance - right ? Why don't you just go ahead and try to change the absolute voltage of the Earth by just one volt. You'll need to set aside a well insulated reference to check your progress. Good luck...

> It really takes two surfaces to have a capacitance
> because there must be a charge differential.

It only takes *one surface* to have self capacitance. The only question might be defining the voltage reference for measuring the static charge. The answer is that a highly insulated voltage reference can be flown in on the third Tuesday of the month for a quick check of the absolute voltage using a very high input impedance voltmeter. It doesn't need to be another 'plate' and the connecting wire can be as long and thin as required to eliminate your concerns about 'ordinary' capacitance.

Another method to meaure the static charge *that is even more clear for the skeptics* is a single port (ground independant) instrument called a foil-leaf electroscope, but the reading will be a bit less accurate.

--

You're apparently missing (or just ignoring) a basic concept.

There is an obvious difference between a large object and a small object when it comes to imposing a static charge (of a given voltage). This

difference still exists even if the objects are far away from any other objects (the charge could be imposed by firing ions at the object from a distance). It is 'harder' to impose a static charge (of a given voltage) on a large object than on a small object. This property is called 'self capacitance'.

The static charge can be (roughly) measured with a foil-leaf electroscope without any ground reference (although in the absence of calibrated Earth gravity it might need to be a newly designed gently spring loaded electroscope).

Do you deny the existence of this property called 'self capacitance' ?

It can be swamped by ordinary capacitance - but it doesn't have to be. The exceptions make my point.

--

The relationship to lightning is that if you have a series connection of a long cable, a sensitive device (usually a semiconductor), and a large self capacitance - then the sensitive device can be damaged when the induced EM pulse tries to charge up the self capacitance (through the semiconductor).

This damage can occur even in that idealized textbook example of an 'immune system' (sic)where '...the whole system maintains a common ground reference voltage during the lightning strike...' (to paraphrase the old claim). The internals of the system *do matter* if such an approach is taken for lightning protection.

The Pro-Am brand of "hamstick" style antennas are white and also are much more rugged, better constructed than the original Hamstick series. IMHO, of course. AND they're less expensive. You can buy them in sets at further savings.

Well, that's one vote. For every one of this sort there is several who swear by them regardless of the fact of their builtin loss. But you should have known better than to expect much of one on 80.

Oh-after using one at work "*for the government*" for several years, I picked up a used one that was priced right (way below the extortionary figure of the mfgr). I was that impressed with its operation. So far I haven't had it in the air. I know how they compare to fullsized dipoles.

> 'Doc

Doc, your experience evidently isn't universal by any means. I had occasion to use two different models for several years on a weekly basis on an 8MC frequency and also on 75 and 40 meters. The setting was two different HF emergency nets, one military and the other amateur. In both instances, over time, the loaded antennas performed very well. I do note that the instructions said they work better when matched at the operating frequency with a tuner, and I found that to be the case. We also had a couple dipoles on the some of them frequencies since we had multiple operations ongoing simultaneously and needed to be able to use all the frequencies without retuning and reloading, so we did informal comparison of the antennas on the air. I could detect no obvious differences although I'm sure there were some that would have been noticeable with S-meter readings on either end of the circuit. Operationally, little difference was noted.
I was well enough satisfied with them that I took the opportunity to acquire one for possible future use when a used one showed up cheap at a hamfest. They were mounted fairly high, one on a building rooftop, the other about 75 feet up a tower as an inverted V.

One more note. I was once acquainted with an individual who was involved with the Alaska State Troopers as a radio tech, and he told me they use T2FD antennas almost exclusively in their HF operations with good results. He said he had built many of them.When I mentioned the necessity of a non-inductive load resistor, he said that it turned out that the inductive resisters worked best! That would be the Radio Shack potted resistors which couldn't have but very little inductance. I once bought and "disassembled" one to see how it was constructed inside. It was a very small diameter, maybe 1/16 to 1/32 in, coil of resistance wire. I

didn't check the inductance on a meter but it was clearly a very small value.

Why would the fiberglass attract lightning over one made from plastic?
I don't see how there would be any difference assuming both antennas
had the same exact shape and sharpness of the tip. Seems to me the one
with the sharpest tip would be the best streamer, and attract the most
lightning. MK

"Reg Edwards"
> The capacitance of the Earth to the remainder
> of the Universe is only 707.4 microfarads.

Rhetorical Question: Does that mean that I could easily change the Earth's 'Ground' reference voltage using a simple circuit driven by 9-volt battery ? 707.4 microfarads isn't very high - it would seem to be a relatively simple matter to impose large voltage changes on a 707.4 microfarad capacitor. I wonder if there might be another factor...

J. Harvey wrote:
"Do you deny the existence of this property called "self capacitance"?"

No. But as described, requiring only only a single surface to have self capacitance, it is hard to square with Terman`s definition of capacitance on page 24 of the 1955 edition of "Electronic and Radio Engineering:
"A capacitor is formed whenever an insulator (i.e., dielectric) separates two conductors between which a difference of potential can exist."

Our subject has been lightning which seems to come from a capacitance although the cloud above earth isn`t much of a conductor until a plasma forms.

J. Harvey says self capacitance can be determined by measuring the static charge.

Why not call the measured quantity "static charge"? We have Coulomb`s law to work with static charge.

Best regards, Richard Harrison, KB5WZI

>directly to the hi-z connector.

These so-called MLB devices are really 9:1 UnUns. Lots of folks write
glowing reports about them. I'm a bit more sanguine. Here's the
deal:

If you have lots of locally generated noise from TVs, Computers, light
dimmers, and other such RFI generating hash; and you aren't able to
erect an antenna at a reasonable distance from the house, THEN an RF
isolation transformer is not a bad idea.

This 9:1 isolation transformer works well especially if your random
wire antenna isn't a substantial fraction of a wavelength. Basically,
it isolates your antenna system away from your house so that you don't
pick up as much e-field garbage as you get closer to the house.

>Put up the longest, highest piece of wire, of any length, the longer the better.
>That is your "best antenna."

Agreed. However some of these folks don't have the room or the
structures to get such an antenna far enough away from the noises in
the house. This is the next best alternative.

J. Harvey wrote:
"It would seem to be a relatively simple matter to impose large voltage changes on a 707.4 microfarad capacitor."

The charge difference between the earth and its ionosphere has been measured at 300,000 volts. Cosmic rays are said to charge the ionosphere and cause the difference. This large potential difference is supposed to incite leakage current , some of which deposits electrical charges on water droplets in the atmosphere.

These phenomena may complicate adding or subtracting from the charge on the surface which relates to the rest of the universe as a capacitor plate.

To change the earth`s charge requires export or import of charge. That doesn`t seem so simple to me but the ionosphere might be used as an accelerating electrode.

Dick,
I certainly didn't intend to imply that my experiences
were universal, I'm sure that they are not. I did intend
to say that the majority of amateur users of the B&W
antennas have been disappointed with their performance.
That's fairly simple to confirm by reading the posts on
this newsgroup from people who have used them.
There can be huge differences between what the military
and amateurs consider 'good', or adequate, performance. The
requirements of the two are not the same, and sometimes not
even close. On the whole, amateurs tend to expect more from
equipment, in particular areas, than the military does. The
military is more willing to accept compromise in particular
areas than amateurs. Nothing unusual about that.
B&W's folded dipole was originally designed for the military
and then sold on the civilian market. As a military antenna
it may suit their requirements just fine, but is certainly a
'compromise' in the civilian market, and one that wasn't
accepted as shown by the number of them you see (or don't see)
in over 40 years of amateur use.

Instead of doing Power-over-Ethernet to power a tower-mounted
802.11b accesspoint/bridge (in this case a Buffalo AirStation or
AirStation Pro) and have to deal with / design for the large
voltage drop, I am thinking of running AC power up the tower
instead.

What is the recommended lightning protection method for the AC line
in this scenario?

Do I just use two standard AC surge protectors, one on
either end of the AC run? One on high next to the accesspoint
to protect the accesspoint, and another on the bottom to protect
the building electrical system?
For the bottom one, do you just connect the Line side [plug]
of the strip to an electrical outlet? Is a standard strip
bidirectionally protective, i.e., able to block surges coming
from the Load side from propagating into the building electrical
system? That is, able to protect the building system from the
"equipment"?

For the Cat5 cable, I assume that you need two TrippLite DNET1
suppressors or similar, one on either end of the Cat5 run, right?

Hello

Only slightly OT - ? about ANTENNA analyzer <hi>. I have just received a new MFJ 269 analyzer with MFJ nickle metal rechargable batteries. The unit uses 10 1.2 volt cells - after charging for 16 hours the unit indicates during power up a battery level of 10.8 - 11 volts. The unit works OK at that level but would like to know if this is a normal/valid reading. MFJ tech support told me it should be around 13.8 volts which in my old grey brain is difficult to understand (10 x 1.2 = 12 < 13.8). Has MFJ come up with new physics power miracle?

Any info is appreciated including other batteries that some of you may be using in this instrument.

Thanks in advance
Ed

c hore wrote:
"What is the recommended lightning protection method for the AC line in this scenario?"

AM broadcast stations use a system which works to keep both r-f and lightning off the a-c supply.

Tower lights have no shunts across them for protection and their failure rates are unaffected. They are fed through steel conduit which adds inductance to the wires and makes the tower a more attractive path for lightning than the wires. Lightning is common-mode, so not much surge voltage appears wire-to-wire. A more sensitive load might need more protection. 3 MOV`s might be appropriate, one from wire to wire, and one from each wire to the conduit.

Across the base insulator, the broadcaster has an Austin Transformer or tower lighting chokes in each tower lighting wire to prevent r-f and lightning currents from passing in either direction. The inductance in tower lighting chokes is low at the power frequency. The resistance is also low, and the tower lighting current is practically unaffected.

The only bypass at the tower side of the Austin Trnsformer or tower lighting chokes is the arc gap at the base insulator. But the Faraday screen in the antenna coupling network takes all the lightning flashes.

On the powerline side of the Austin Transformer or tower lighting chokes, conventional arresters shunted with a-c capacitors of the type sold for the purpose bypass each wire, including the neutral wire, to ground. The wiring is connected between tower site and breaker box, using more steel conduit. There are more arresters and capacitors at the breaker box.

Tower lighting chokes are probably about 1000 ohms reactance at the r-f frequency. J.W. Miller used to sell tower lighting chokes at a reasonable price and I`ve used many in lightning protection that had nothing to do with tower lightninmg. They did the job when nothing else worked without them.

Best regards, Richard Harrison, KB5WZI

No battery has a voltage that stays put regardless of the current drain or state of charge, although NiMH cells have a more constant voltage than, say, alkaline cells. The voltage of a freshly charged NiMH cell is 1.3 - 1.35 volts. (The voltage can be considerably higher than this while charging.) When you begin discharging one with moderate current drain, the voltage rather quickly drops to about 1.25 volts, and it very slowly drops from there to about 1.2 volts as the cell discharges. It stays between about 1.25 and 1.2 volts for nearly the whole discharge period. Just before the cell is completely discharged, the voltage drops quite rapidly below 1.2 volts. At 1.0 volts, there's very little energy left, and the cell is considered fully discharged. NiCd cells have the same characteristics in this regard.

Sounds like you have a shorted cell, or perhaps two -- or maybe the voltage isn't being reported correctly. It's easy to check for this with a voltmeter.

Thanks for the replies from all.

Indeed, two of the batteries are indicating 0 volts, the others are around
1.35 - 1.38 volts.

1582. Oil in dummy loads vs. SWR.

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-22 19:13:35 UTC
From: jeff <wd4nmq@earthlink.net>
Message-ID: <3D3C599F.732499B6@earthlink.net>
Source record: 138124
Cross-posted to: rec.radio.amateur.antenna,rec.radio.amateur.equipment

I feel that I am once again going to open the old debate which oil to use in a dummy load for heat conduction.

But, that is not my question. Mine has do with the oil's effect on SWR vs. frequency.
The reason I ask this I have a Dentron Big Dummy I bought at a hamfest many years ago and have seldom used it, then only on HF, do to being "out" of ham radio for a while. I have now been using it to check out several old club rigs and I have noticed a big difference between it and the club's Heath Cantenna.

The SWR increases as frequency increases. At 80 thru 15 meters there is no SWR indication with just a little at 10 meters. No problem. But, at 2 meters the SWR is 3:1. The Cantenna has no indicated SWR at 2 meters. Infact, it states on the can SWR <1.5 up to 300 mc.

The Dentron has no frequency range on it.

I took the lids off and both had an identical looking carbon resistor. But, their oil was definatly different. The Cantenna was perfectly clear while the Dentron was much darker.

So, does anybody know anything about the Dentron Big Dummy and it's frequency range? What kind of oil it shipped with?

I started to take the lid from each, drain and clean them and swap them to see if the range follows the oil or the resistor. But, that is to much work.

1584. 3/2-Wave Dipole & 75 Ohm Quarter-Wave Matching Section

Newsgroup: rec.radio.amateur.antenna
Date: 2002-07-22 19:29:28 UTC
From: ddelakas@midway.uchicago.edu
Message-ID: <s2Z_8.49$Z4.13396@news.uchicago.edu>
Source record: 138126

Greetings, all. Apologies if this particular horse has been previously flogged.

I am interested in mounting a 3/2 wave 20 meter dipole on my roof (45 feet up, urban setting, space limitations). I plan to cut it for 14.150 MHz since I spend most of my time on 20 M phone & PSK31. Using the formula length (ft) = 1460/f, the dipole will be 103 ft 2 in long.

I plan to feed it with RG213. As it will be a monobander, I would like to add a quarter-wave matching section of RG11. I figure the matching section length in feet to be = ((246)*vf)/f = (246*.66)/14.150 = 11 ft 6 in roughly.

So far so good. I have the following questions:

1. What is the "power rating" of ordinary RG11? I usually run abt. 600 watts on phone.

2. Is it true that I'll get a better match if I add the RG11 matching section AFTER a run of 1/2 wavelength (roughly 23 ft) of RG213 attached directly to the dipole?

3. Are F connectors robust enough to handle Midwest winters? The only ways I see to join the RG11 and the RG213 are with F-to-UHF / UHF-to-F adapters -or- solder-n-smear (with vinyl tape & Coax Seal or similar product).

Thanks for taking the time to read this post es 73.

Oil probably does not affect SWR that much.
Just pull the resistor out of the oil and see if SWR changes.
Your experiments verify that the resistive component is 50 ohms.
The problem is likely in the inductance of the resistor and it's
mounting structure. Resistors that "look alike" often aren't.

The Heath Cantenna did not come with oil. A club I belonged to filled
it with "Chevron Flo-Cool 180" which worked great. Fortunately we had
a free source of that product, as it is not cheap. Mineral oil seems
to be the fluid of choice.

IIRC most of those loads had the load resistor surrounded by a
tapering shield -- I assume that acted like a tapered coaxial
line that "matched" the load resistor impedance along its
length. I wonder if the different oils have different dielectric
constants--
that could explain the differing SWR readings at VHF frequencies
(assuming the load is non reactive to begin with).

The W9INN antennas will fit your bill. I use a 80/40 meter version
with full power (Alpha 99) and narry a problem. They have a variety of
multi-band dipoles, some as short as 60+ feet.

Check out the add in each month's QST, or see

How do you seal the ends to eliminate air movement?

Do you use expansion couplings to handle different rates of movement
between wood siding, masonry foundation and earth?

Also, I believe there is a switch inside the unit. Regular batteries are
1.5 volts but If you are using lower voltage batteries, NiCad, NiMH etc, you
need to throw the switch to work with the lower voltage.

...such as....SELF CAPACITANCE !!!!!!!

My point was that the 'self capacitance' of the planet Earth is many, many, many, many orders of magnitude higher than 707.4 microfarads.

Otherwise, it would make a very poor 'ground'.

Any unit using alkaline batteries that won't work at 1.2 volts/cell is very poorly designed. At moderate current drains, up to 2/3 of the energy in an alkaline cell is delivered at a voltage of 1.2 volts or less. You have to discharge an alkaline cell to about 0.9 volts or less to extract all its energy, so a device designed for use with alkaline cells should be able to operate properly down to this voltage.

Yet any elementary physics textbook shows this calculation. See for
example problem 29-2, Weidner & Sells, _Elementary Classical Physics_,
Vol. 2.

I imagine that an analysis of the Earth's ability to absorb charge
locally would have to consider factors beyond the simplistic model of
the Earth as a perfectly conducting sphere having only the property of
capacitance.

The idea of charging the Earth with a 9 volt battery is an intriguing
one. Especially in contemplating the connection of the other terminal to
the Universe. That would surely require Ether Grease, in short supply
these days.

Hi Roy

I agree. In this case the system is designed pretty well as it was working at 10.8 volts with 2 of 10 batteries completely zeroed. The low voltage alarm message is set for around 9.4 volts.

BTW, I purchased the unit from W0BW (www.w0bw.com), not only did they have the best price, it was shipped same day, and when notified about the batteries being defective, immediately put two in the mail. Top notch service IMHO. But we all know that all ham radio retailers are beyond reproach (right).

Hi Roy,

I have been attending Nanotechnology seminars where one manufacturer
has built buckytubes at lengths up to several centimeters (a buckytube
being a carbon ring, stacked upon copies of itself). That they have
achieved this length is remarkable for the range of scale (from nano
to centi). They hope to build them long enough to use with earth
"tethered" satellites (charge transfer with long tethers in space was
conducted several years ago).

One of the interesting facts about conduction at the nM scale, is that
it takes more than volts to get a charge to move (or it takes more
volts than your simple equations would offer). The carbon buckytube
is conductive enough (over the short-haul), but fitting it with a
connector to mate to the source is a bitch.

The proper quote is "...using a **simple circuit driven by** 9-volt battery...".

> Especially in contemplating the connection
> of the other terminal to the Universe.

I've already addressed this rather trivial technical concern in a previous posting: "...the charge could be imposed by firing ions at the [Earth] from a distance...". The overall circuit might need a dozen D-cells and be in low Earth orbit.

My point (!) is the extremely low amount of electrical energy that would be required to change the voltage of a 707.4 uF capacitor by one volt. Even several tens of kilovolts are *well within* the capabilties of "batteries" (perhaps alkaline).

Several tens of kilovolts are interesting in that such a charge should be sufficient to make every 'foil-leaf electrometer' on the planet stand up (not to mention making everyone's hair unmanageable).

Something smells funny in '707.4uF la la land' - doesn't it ?

Maybe the Earth is a very very leaky capacitor. (?)

Can someone tell me the measured resistance of the two
"phase inductors" on this antenna? The top one is showing
open on mine while the bottom one reads 0 ohms. I suspect
the top one is bad, but before I give RF Parts $17.50 for it,
I'd like conformation on my suspicion.

Thanks!

Jeff,
The oil shouldn't affect SWR if it is clean,
not contaminated with 'stuff' that might change
it's conducting properties. It sounds like the
oil in your Dentron dummy load may be contaminated,
or maybe has changes chemically if it's ~that~ old.
Try dumping it, cleaning the container, and refill
with mineral oil.
'Doc

Yep, looks like we could charge the Earth up to 10 kV with the energy in
a car battery.

Incidentally, I experienced first-hand the phenomenon of charging by
spraying ions. It was once my fate to solve some problems with the
design of a 30 kV CRT supply. The production supply was potted, but for
prototypes we built a Plexiglas box and filled it with Freon. Immersing
the prototype in the Freon prevented corona. But I had a lead sticking
out of the bath for measuring the voltage, and it was fizzling away. I
ignored it -- until I touched something grounded. The ion spray had
charged me to quite a potential.

Try looking for some white PVC heat srink at an electronics supply. One of the local shops has about 8 different colors of 1/2" 50% in 3 foot. You can carefully cut and peel off the black heat shrink and replace it with the white.

I put a new antenna mount on my honda crv today. the mount is about 3' angle aluminium stock, with a hamstick mounted at the top. the aluminium is held against the spare tire by 2 long bolts, and the bolts are anchored on the back of the tire mount by 2 other pieces of stock.

when i used this antenna on my blazer, it was a perfect match at 14.2 mhz. now it matches 1:1 between 13.2 and 13.7 mhz. lengthening and shortening the whip does nothing, since the swr climbs to over 5:1 in the 20 meter band.

although the swr is high, signal reports find the audio is clear with no signs of distortion (so no rf getting into audio). i did not try a ground but the lack of distortion and rf seems to indicate this probably wouldnt help.

anybody have any ideas? thanks all...

Better yet, get flat brown, green and black spray cans and camoflage it.
Just don't bridge over any of the insulating rubber gaskets with paint and
you should have no problem.

God luck,

Bill, W4WNT

[According to the calculations ?] I take that result as indicating that there is something is wrong with the theory or its application. Perhaps my 'gut instinct' is improperly programmed, but the Earth strikes me as being *a lot* more stable (voltage wise) than only 707.4 uF.

If I understand your configuration, you have an 11 ft. antenna fed 3 ft.
up from the base. Of course it is going to resonate at a lower frequency
than an 8 ft. antenna and your feed system somewhat resembles a gamma match.
What might be a solution is to use a 17m or 15m hamstick for 20m.

If you can get your hands on the Scientific American cd The Amateur Scientist, The Complete 20th Century Collection, there are two articles by C.L. Stong you might find interesting: May 1957, "Experiments Which Show That The Earth Functions
As An Electrostatic Machine", and October 1974, "Electric Motors Are Powered By Electric Field Of The Earth." Mr. Stong considered the earth, atmosphere, and

ionosphere as a big, leaky, capacitor that keeps itself charged through the action
of lightning storms. Put a large piece of metal high up. Leave it there long enough to
get a charge. Bring it down and fry yourself. Sounds fun.

It will, but you are better off using a pigtail made of LMR 400-UF
(flexible) and about three turns around the rotor That's what I use and
there are 4 runs that loop around the rotor.

Done properly (with 3 or 4 turns) inside guides the only thing that happens
is the loop gets a little bigger, or smaller.

I prefer to use that plus the flexible stuff to get around the rotor.

The RF is fed into the resistor, which is the actual dummy load.
The oil is only there to dissipate the heat.

Since the topic of "cantennas" has come up, I though I'd ask a question that came up before:

How much does using oil multiply the resistor's effective wattage rating? For example if I used a 2W resistor and put it in a can of oil, how much can I dump into the resistor?

This is NOT a simple question.
Ultimately, what goes in must come out.
So, one limit is sorta proportional to the relative surface area,
assuming you've got good convection and perfect conduction.
The thermal mass of the oil slows things down. That's why peak power
rating is higher than the average power rating.
Another limit is the thermal resistance of the system.
The oil is only one part. If you use a film resistor, you'll get much
better thermal contact to the oil than if you used an AB carbon
resistor
with the bakelite surface (2W resistor). At some power level, the
resistor
is gonna explode, no matter how much oil it's in.

The resistor in a cantenna is probably worth 50-100W in air.

Or it's mounting method.

I took the Dentron resistor out of the oil, dried it and tried 2 meters into it. Still had 3:1 SWR.
Now, the resistor mounting in the Dentron had only a piece of flat metal running from the can lid, ground, to the bottom of the resistor. While the Cantenna's resistor is inside a grounded aluminum tube which connects to the bottom of the resistor via three screws.

So what Peter wrote may be along the right line. May do some more testing.

Any resistor in a transmitting antenna is just a way to dissipate power
without radiating RF. I.e. a bad idea. Cut out the resistor and use
an ATU. Result - more radiated RF.

Hi Jeff,

Mounting method should include a close examination of the connection. Given you have earlier reported the color of the oil as dark; this could be evidence of contaminants, scale or bits sloughed off from the resistor if/when it was over-powered.

This sounds obvious, but did you measure the load's resistance (at DC)? How about when it is immersed in oil?

This is simply accomplished with the handy VOM, but you should go further and measure the resistance over a range of applied voltages that span a significant range of power. However, finding power sources to deliver an amp at up to 100V is rare. The resistance of a resistor varies with current applied; and only the sub-watt models come close to zero temperature coefficient (and power resistors are the most likely to fluctuate wildly).

Another factor is that the Dentron may have never been designed for 2 Meter operation (although I cannot imagine why not).

Pickup only 20 miles south of downtown Houston in Friendswood, TX.

Mosley S-402, 2 element 40 meter beam on a 20 foot boom, max element length 44 foot. Some mildew on aluminum but otherwise good and complete. $50.

Mosley CL-33 triband beam. 18 foot boom. Judging by the good condition of the trap plastic end caps, this one has spent most of its life in storage on the ground. $50.

Wilson Electronics 10 meter mono-bander. 5 elements on a 26 foot boom, gamma match. Appears to be complete and in good condition. $50.

Qand antennas/parts. One complete 4 element quad on a 28 foot boom plus a smaller 4 element quad on a 20 foot boom. Cast aluminum brackets. A few of the fiberglass rods for the smaller one will need to be replaced. $50 for all.

I guess worse case scenario you could go and buy white (or almost any
colour) shrink tubing by the foot from most electronics components
suppliers and then cover the coax with it.

Would surely be a lot cheaper than a specialized white coax.

My 2 cents worth...

Yea, I measured it with a Fluke DVM and it measured 52.xx ohms. The Cantenna measured 48.xx ohms.

I might, if I get time, build up the resistor mounting to be like the Cantenna.

Right now it works ok on HF. Just a slight, <<1.2 at 10 meters, SWR. So it's ok for what little I use for. The occational checking out of older rigs.

Does anybody know a source for resistors like that used in the Cantenna and Dentron? They are about 1" in diameter and 5-to-6" long.

Anybody know the exact wattage of the Cantenna resistor?

Pick up a new clean gallon can from my pal at Sherwin-Williams, some mineral oil, hmmmm.

Hi Mark,

Coax is/can be white for two reasons.... coloring in the outter jacket material and by virtue of it's material of construction... ie teflon PTFE type coax.

It's sold by Belden... the RG-188, RG-58 ptfe teflon types... a bit more lossy, but very nice stuff. Motorola used to supply it with their 800 Mhz commercial, mobile radio antenna kits. You can still buy it from Newark, Talley, Comtelco and probably The Wireman. I've placed order with all the mentioned in the last two months, all came through perfect the first time out.

Years ago... circa late CB boom, Columbia used to make a vinal light Grey "Superflex" type coax. There were also some decorator colors made... red, blue and white by overseas mfgrs. It went away when the CB boom came crashing down... although it was quite popular at the time....

Now with the Audio Monster Cable type hype flowing into the radio market, I have again seen clear vinal jacket coax (which is not RG-400 or RG-142 Teflon PTFE types) sold through some CB (and Ham) stores.

It's real crap, I've measure the shielding and loss... the stuff makes almost as good a radiax antenna as it does coax. I would not trust it for anything above 27.405 Mhz... certainly not at 6 meters and higher.

So you have it... the teflon is probably not what you want, but it works and is very expensive. It's not practical for long base station runs.

cheers

Looks like they are missing 5%-13% of one S-unit.

1655. Opinions wanted: Cushcraft A2706S vs MFJ1768

I am considering buying a dualband yagi for 2m and 70cm. I'm considering either the Cushcraft A2706S or the MFJ1768. Both are the same price ($80), but the MFJ is 7 elements on 70cm vs 3 elements on 70cm with the Cushcraft.

Does anyone have experience with either of these antennas? I'm leaning towards the MFJ because of the extra elements, but wanna know what other people think.
